Alcohol in Drug Stores.—The State Commissioner of Excise of New York has made the following ruling in the matter of filling prescriptions by regular pharmacists, where the same contains alcohol or other liquor, *viz.:* That where, in good faith, a pharmacist is obliged, in the preparation of bona-fide medical preparations, to use alcohol or other spirits in the compounding thereof for the purposes of medicine, it is not a violation of the liquor-tax law so to do, although in a town where such medicine is prepared or prescription filled, the sale of liquor, as such, is prohibited under the different questions submitted under the local-option provisions of the liquor-tax law.

Board of Pharmacy, as Amended.—Mayor Strong has accepted the bill amending the Greater New York charter in the matter of appointment of a Board of Pharmacy to examine and register pharmacists in the city. The amendment gives the appointment of two of the members of the board to the New York College of Pharmacy, of a like number to the Kings County Pharmaceutical Society, and of one to the German Apothecaries' Society. Members of the board are required only to be competent pharmacists Three-fifths of the net receipts are to go to the New York College of Pharmacy for its library fund, and two-fifths to the library fund of the Brooklyn College of Pharmacy. Penalties collected are to be divided between the institutions in the same proportion.

Free Baths in Boston.—The latest undertaking of the Metropolitan Park Commissioners is the building of a bathing pavilion at Revere Beach, within easy reach of the city limits. It will have accommodations for 1000 bathers. They have designed the most elaborate and complete bathhouse on the Atlantic coast. The landscape engineering in the vicinity of the bathing pavilion is the work of the late Charles Eliot, son of President Eliot of Harvard College. Every one of the 1000 bathers will have the benefit of privacy, and will reach the beach by means of a subway. The building will have every modern convenience, such as toilet-rooms, retiring-rooms, a large room for the distribution of bathing suits, electric lights, and a room for the storing of valuables. A big laundry will be capable of washing and drying 400 suits an hour. Only a nominal fee will be charged for the use of the bathing suits, which will be the only expense connected with the pavilion.

Life Insurance Doctors Discuss the Effects of Beer and Athletics.—The effects of beer drinking and violent exercise, such as bicycle riding, football, and track athletics on longevity were discussed at length at the annual meeting of the medical directors of the life insurance companies recently held in New York. Dr. Rogers of the New York Life said he had had occasion to make some study of what happens among persons engaged in the manufacture of beer, defined generally as brewers. It is a curious fact that the mortality among the proprietors is about as high as among the workmen, showing that they are all given to copious libations. Another curious fact is that the data indicates that Urtellos's point, emphasized by Dr. Bernacki, that mortality is very high at advanced ages, is very well borne out. The mortality is strikingly low among brewers in early years. Up to forty or thereabouts, brewers seem to be about as good risks as pretty much anybody else. After forty the mortality rises very high, and at fifty-five or sixty years of age about three brewers may be expected to die where one average person dies. Dr. J. C. Young of the Mutual Benefit Life Insurance Company said that football, bicycling, and other athletic exercise greatly impaired a person as a risk. He had observed that after violent exercise the presence of albumen was discovered in the urine.

SPECIAL ARTICLE.

THE REPORT TO THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK OF ITS COMMITTEE ON THE ABUSES OF MEDICAL CHARITY.

(Transmitted May 24, 1897.)

MR. PRESIDENT AND GENTLEMEN: In accordance with a resolution acted upon at a meeting of this Society held in October last, a committee of eleven members was appointed to devise means for the control or correction of the abuses of medical charity now existing in this city. This committee was made up as follows: J. H. Burtenshaw (chairman), A. B. Ball, Hermann J. Boldt, E. S. Bullock, Henry D. Chapin, Carter S. Cole, Alexander Hadden, William M. Polk, W. Washburn, W. H. Weston, and F. H. Wiggin.

At the first meeting of this committee two steps were decided upon: (1) To ascertain the sentiment of the governing boards of the different dispensaries regarding the proposed effort to check indiscriminate dispensing of medical aid, and (2) to communicate with the Charity Organization Society of the City of New York with the object of ascertaining if a system might be devised whereby the worthiness of applicants for dispensary treatment might be investigated and reported, and if its cooperation might be relied upon to this end.

As a result of the last-named resolution, the fact was made known that the Charity Organization Society would willingly cooperate with this Society along the lines proposed, and that it would place its general offices and staff of assistants at the service of the County Medical Society free of cost, provided the extra expense attendant upon the proposed investigations was met by contributions from other sources.

In order to determine to what extent the cooperation of the dispensaries might be relied upon, a copy of the following letter was sent to the president, secretary, or physician-in-charge of each of the ninety-five dispensaries located in this city:

"DEAR SIR: The committee recently appointed by the Medical Society of the County of New York to devise means to correct the abuses of medical charity now existing in this city respectfully asks for answers from you, in your official capacity as an officer of one of the free medical dispensaries, to the subjoined questions:

"1. Does the governing board of the dispensary approve of the movement to abolish or regulate the abuse of medical charity?

"2. Will the governing board cooperate with the committee of the Medical Society of the County of New York and endeavor to dispense free medical treatment only to those applicants that are deserving and unable to pay a physician for such services?

"3. Will the governing board agree, at such time as called upon, to display in conspicuous places in the dispensary a placard reading somewhat as follows: 'On and after [date] the case of every patient applying for free medical treatment at this dispensary will be investigated, to determine if the applicant is deserving of free medical service,' providing such agreement is not to be construed as binding the dispensary to make such investigations on its own account.

"On behalf of.................. DISPENSARY.

"(Signed)"

Replies to this letter have been received from 76 dispensaries. Of the 19 dispensaries ignoring the first circular letter, and a duplicate sent out on the 1st of April, 5 are homeopathic, 2 are under the supervision of the Department of Charities, and the remaining 12 are either private or church institutions at which but a small number of patients living in the immediate vicinity are treated. These replies were affirmative, or conditionally affirmative, to all three questions, with the exception of those received from the Dispensary of St. Mary's Free Hospital for Children, located at 435 and 437 Ninth avenue, and the Out-Patient Department of the New York Hospital, 21 West Fifteenth street.

The Dispensary of St. Mary's Free Hospital for Children treated 7101 patients during the year 1896, and during the same time the Out-Patient Department of the New York Hospital treated 9803 new patients, who made 45,832 visits to the dispensary, a majority, it is understood, being required to pay one dollar per month for the treatment received regardless of financial condition.

At a succeeding meeting of your committee it was made known that a committee having in view the same object as its own had been appointed by the County Medical Association, and that an organization known as the New York Medical Society for the Advancement of the Practice of Medicine had been formed, and on March 22d had caused to be introduced in the Legislature of the State a bill embodying certain reforms in the management of dispensaries in this city. It was the opinion of your committee that certain features of this bill were of too radical a nature to allow of its becoming a law at the present time; that any enactment designed for the control of dispensaries should apply to the entire State rather than to the city of New York alone; that, in the former case, the supervision and control of dispensaries should be placed in the hands of the State Board of Charities; and finally, that, as far as practicable, the efforts of the different committees formed for the same purpose should be directed alone the same lines. Your committee feels that great credit is due the members of the New York Society for the Advancement of the Practice of Medicine, and the members of the committee of the County Medical Association for their efforts toward the control of the charity abuse, and thanks for their hearty cooperation with your committee toward this end.

The bill introduced in the Legislature by the first-named organization was ultimately amended so that its provisions read as follows:

SECTION 1.—By this act a dispensary is defined to be any institution, agency, or place, society or association, whose actual, or alleged, purpose it is to furnish gratuitously or at a merely nominal price to indigent, needy, or other persons not resident therein, medical, or surgical relief, advice, or treatment, medicine, or orthopedic, or other appliances.

Section 2.—On or after the first day of October, 1897, it shall not be lawful for any one to establish, conduct, or manage at any place in this State a dispensary not duly incorporated as such under the laws of this State, or not connected with another corporation and licensed by the State Board of Charities.

Section 3.—In no case shall a dispensary be established, carried on, or conducted in any place in this State commonly known as a drug store, nor in any place or building in the State defined by law, or by an ordinance of a Board of Health, as a tenement house.

Section 4.—It shall not be lawful for any person or persons to display the word "dispensary," or to cause the same to be published in any form, or in any manner, in order to attract any indigent, needy, or other person to any dispensary not duly incorporated or licensed, as provided in Section 2 of this act.

Section 5.—Any person who shall by means of any wilful false representations on his or her part obtain at any dispensary medical or surgical relief, advice or treatment, medicines, or orthopedic or other appliances, or any person who shall wilfully violate any of the provisions of this act shall be guilty of a misdemeanor and, upon conviction, shall be required to pay a fine of not less than fifty nor more than two hundred and fifty dollars.

Section 6.—The State Board of Charities is hereby empowered to make rules and regulations and to alter and amend the same when in its opinion necessary, in accordance with which indigent, needy, or other persons shall be given medical or surgical relief, advice or treatment, medicines, and orthopedic or other like appliances by such duly incorporated or licensed dispensaries, and the said Board is empowered, a chance for a hearing having been given, to annul the incorporation, or suspend the operations or to revoke the license of any dispensary for wilful neglect or failure on the part of its managers, trustees, officers, or employees to comply with the rules and regulations so established by said Board, but nothing in this act contained shall be considered to mean that said Board shall have power to determine the particular school of medicine under which the dispensary shall be conducted.

Section 7.—All acts or parts of acts inconsistent with the provisions of this act are hereby repealed.

Section 8.—This act shall take effect on the first day of October, 1897.

This bill was passed without a dissenting vote by both Senate and Assembly on the 14th day of April last, but up to the present time has not received the signature of the Governor. This fact is peculiarly unfortunate as, according to the law of the State, all bills that do not receive the approval of the Governor within thirty days of the adjournment of the Legislature lapse and become void, and in the present instance this time limit expires at twelve o'clock to-night. This failure on the part of the Governor to approve the bill can perhaps be attributed only to pressure of official business, as at the date of adjournment of the Legislature, on April 24th, there were more than 700 enactments awaiting his signature.

The President of this Society, your committee, the President of the County Medical Association and the members of its committee, and the members of the Society for the Advancement of the Practice of Medicine have thoroughly appreciated the importance of this bill and the necessity of its becoming a law, and every influence at their command has been brought to bear toward this end. As no opposition was made to the passage of the bill in either branch of the Legislature, and as the profession, not only in this city, but throughout the State, is practically unanimous in commending its main features, the sense of disappointment is the more keen at the failure of the Governor to stamp the measure with the seal of his approval.

In anticipation of the bill being signed, the State Board of Charities, at a meeting held on the 14th of April last, appointed a committee of three of its members to hold public meetings immediately after the bill became a law for the purpose of receiving suggestions regarding the promulgation of rules for the management of dispensaries, and it was the intention of your committee to ask for authority from this Society to represent it before that body. In view of the failure of the Dispensaries bill to become a law, your committee is in a position only to recommend that the Committee on the Abuse of Medical Charity be continued indefinitely, and that it be empowered to take such steps as may appear to it advisable toward obtaining future legislation in the direction of correcting or controlling the medical charity abuse.

In conclusion, your committee expresses the conviction that there is no species of charity so beneficent, so far-reaching, or so generously bestowed as true medical charity, and that nothing could be further removed from its wish than that it should be curtailed or kept from the reach of the deserving poor; but it has been so conclusively demonstrated that there exists such gross and unpardonable abuse of that charity on the part of those who are not entitled to it that it has become imperative to adopt radical measures for the suppression of that abuse, and at once.

Respectfully submitted.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE ATTENDANCE AT THE COMING MEETING OF THE AMERICAN MEDICAL ASSOCIATION — COMMENCEMENTS OF THE WOMAN'S MEDICAL COLLEGE AND MEDICO-CHIRURGICAL COLLEGE — PHILADELPHIA PEDIATRIC SOCIETY—SECTION ON GYNECOLOGY OF THE COLLEGE OF PHYSICIANS—FREDERICK DOUGLASS MEMORIAL HOSPITAL — CHANGES IN THE FACULTY AT THE PHILADELPHIA POLYCLINIC—DR. WILLIAM THOMSON.

PHILADELPHIA, May 22, 1897.

As the time for the coming meeting of the American Medical Association approaches it grows more and more apparent what an important convention this is destined to become, both in the number of members in attendance, for it is now fully expected that the early anticipations for the attendance of three thousand will be realized, and in the importance of the scientific business transacted, from a synopsis of which it is evident that every field of medicine and of surgery will be fully covered. In some instances, it is to be regretted, there is such a plethora of material for thought and discussion, that the scientific value of the proceedings is threatened. However, the number of "read by title" papers will, as is always the case with these large gatherings, in all probability allow ample time for the discussion of those subjects which are presented at length.

On Tuesday, June 1st, there are to be special exercises held at the Academy of Music, commemorative of the fiftieth anniversary of the founding of the Association, at which addresses of historical interest will be delivered by prominent members.

In addition to the entertainments already provided for the visitors it is now announced that there will be an elaborate garden party on the campus of the University of Pennsylvania, tendered them by Provost Harrison, of this institution.

The forty-fifth annual commencement exercises of the Woman's Medical College of Pennsylvania were held in the Academy of Music, on May 19th. Degrees were conferred upon the members of the graduating class, which numbered twenty-eight, by Lucretia M. B. Mitchell, of the Board of Corporators, and an address delivered to the graduates by Professor Frederick P. Henry, of the Faculty. The annual dinner of the Alumnæ Association took place the same evening at The Rittenhouse.

On May 18th the graduating exercises of the Class of 1897 of the Medico-Chirurgical College took place in the Academy of Music. Sixty-six members of the class received their degrees from the President of the Board of Trustees, C. William Bergner, and were addressed by Professor William E. Hughes. The Alumni Association of the College held its yearly banquet at the Hotel Stratford, on the evening of May 17th, at which speeches were made by Judge William B. Hanna, the Rev. C. Ellis Stevens, Rufus E. Shapley, C. William Bergner, Dr. John W. Croskey, and Dr. John V. Shoemaker.

At the last meeting of the Philadelphia Pediatric Society, held on May 18th, Dr. S. W. Morton presented an interesting discussion of the question of paralysis in children as a sequence to measles, and reported a case of this character; during the course of this paper, which was discussed by Dr. J. P. Crozer Griffith, Dr. Morton took occasion to draw attention to the dearth of text-book literature which exists on this topic, although here and there monographs on the subject may be found. A paper was also read by Dr. D. J. Milton Miller, detailing the history of a case of infantile scurvy, and discussing this rare disease.

At the last stated meeting of the Section on Gynecology of the College of Physicians, on May 20th, Dr. John C. Da Costa reported a celiotomy, in a woman five-months pregnant, for the removal of an ovarian cyst, and with restoration to its normal position of the retroflexed and adherent pregnant uterus, resulting in recovery without miscarriage, also of dormoid cyst, of apparently rapid growth, and weighing twelve pounds, removed by abdominal section; and a large polyp, from a woman of advanced years.

Dr. J. Montgomery Baldy exhibited a specimen of a varicosed condition of the veins of the broad ligament, which he removed on account of the intolerable pain suffered by the patient; the operation resulted in a complete cure of the symptoms complained of. Dr. Baldy suggested that this condition would probably explain the cause of many of the ills in women, in which the etiology is unaccounted for.

The first commencement exercises of the class of nurses of the Frederick Douglass Memorial Hospital occurred on May 21st, when two nurses who had completed their course of training in this institution were graduated. The event was one of interest in that it marks the end of the second year's existence of a hospital devoted exclusively to colored people, and engaged in the training of colored woman as nurses. The hospital, which is in a flourishing condition, was founded by Dr. N. F. Mossel, a well-known colored practitioner of this city, and is largely supported and managed by persons of this race. That there are many negro women desirous of taking up trained nursing as a calling is shown by the fact that there are at the present time more than one hundred applications on the waiting list for admission to this hospital's training school.

The resignation of Dr. Charles W. Burr, Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic, has been accepted by the trustees of the school. Dr. Burr's successor to the Chair has as yet been unnamed. In this institution Dr. G. Hudson Makuen has been elected Professor of Defects of Speech, a position recently created; and Dr. T. B. Schneideman to the Chair of Diseases of the Eye.

Dr. William Thomson, who recently resigned the Chair of Ophthalmology in the Jefferson Medical College, has been made Emeritus Professor of this branch, in recognition of his long and valuable services to this institution.

The Maine Medical Association.—The forty-fifth annual meeting of this society will be held at Portland, Wednesday, Thursday, and Friday, June 2d, 3d, and 4th.

OUR VIENNA LETTER.

[From our Special Correspondent.]

MEDICAL STUDENTS AT THE UNIVERSITY — POST-GRADUATE COURSES DURING AUGUST AND SEPTEMBER—THE INTERNATIONAL CONGRESS AT MOSCOW.

VIENNA, May, 6 1897.

THE official University announcements for the summer semester have just been published, and with them the number of students registered during the winter session. Altogether 7026 students were in attendance in all departments. Of these, 2752 were registered in the medical department, 1592 as regular students, 425 as special students, and 735 as taking post-graduate courses. Of the post-graduates, 118 are from America, North and South, most of them, however, from the United States. This is a larger number of post-graduates than are registered from any other country, even Austria itself, and serves to show how popular Vienna is with American medical students.

The proportion of medical to other students is somewhat more than one to three, and is about the proportion that exists everywhere in Europe, and about the same as occurs in our own universities. It is not surprising that complaints are heard on all sides that the profession is becoming overcrowded when more than one-third of all those receiving a university education are devoting themselves to medicine. The figures given do not represent the whole truth here on the Continent, however, for a certain number of those included among the philosophic students will later turn to medicine as the utilitarian completion of their education.

Among the announcements that seem of interest is that of the continuance of post-graduate work during the months of August and September. Somewhat as an experiment, a certain number of courses were continued during last summer, and with such satisfactory results that more are to be added this year. Visitors to the congress at Moscow, in August, will have an opportunity to do some work in Vienna before and after the congress, if so inclined, and may thus gain an idea of the very practical teaching methods of the Vienna school.

Another announcement is to the effect that, beginning with the winter semester in October of this year, the philosophic courses of the University will be opened to women on the same conditions as to men. Their admission to the medical department is put off for a time until certain contemplated reforms in the medical course are effected. Since the recent "promotion" of a woman to the Doctorate in Medicine the admission of women to full university privileges has been looked forward to with a good deal of assurance. The concession is commented on very favorably from nearly all sides, and though some of the opinions expressed show that there are certain ones who are inclined to be dubious as to the outcome of higher education for women, there has been no actual opposition to the movement. Women from foreign countries are excluded from these privileges, however, as students must be natives of the Empire, or at least *bona-fide*, permanent residents, and must have made their preparatory studies successfully in one of the Austro-Hungarian gymnasia.

The reforms in the plan of medical studies spoken of have been in contemplation for some time. Certain purely scientific studies with only slight bearing on medicine, as mineralogy, zoology, and botany, are to be dropped from the course. The examinations in anatomy, physiology, chemistry, etc., which up to now could be put off till the last year, will have to be passed before the practical clinical work is taken up. Finally, one of the five years of the medical course will have to be passed in hospital service before the candidate will be given a license to practise. All the details of the proposed changes are not yet definitely settled, but these are the general lines along which they are to be made. At the same time the question of the remuneration of professors is to be definitely settled. The present unsatisfactory method (at least to some members of the faculties) of being paid according to the number of students in attendance on their courses is to be exchanged for the fixed-salary system. As things are now, some of the really scientific workers, but whose lectures involve theory rather than practice, are very unsatisfactorily paid because their courses are not attractive to students, while some of the lesser lights, particularly some of the specialists or professors whose examinations are known to be especially hard, are very handsomely paid by the crowds that flock to their lectures.

One of the most striking things in Vienna, I think, especially for the American medical student, is the autopsy-room of the *Allgemeines Krankenhaus* (General Hospital). Certain feelings of what one cannot help but call false respect, not for the dead but for dead bodies, make autopsies even in interesting cases comparatively rare with us. Even in State institutions too often the same mistaken feelings dictate that autopsies shall not be public. The result is that many a young doctor begins practice after having seen but two or three autopsies and with the haziest ideas as to the macroscopic appearance of diseased organs. The value of exact notions as to pathologic, anatomic lesions cannot be overrated. The false sentiment that now practically prevents this is of too serious importance to be permitted longer to exert the sway that it does if real progress is to be made in practical medicine. It is to doctors themselves that medicine must look for the gradual modification of the ideas that dictate the present policy.

Here every interesting fatal case comes to the autopsy-table. The practical importance of it for diagnostic purposes is evident any and every day. Out of the eight to fifteen daily autopsies at least one sometimes two or three reveal conditions that have been missed after the most careful diagnosis. Here are some samples of the last ten days. Clinical diagnosis: "Senile marasmus with hyperscoliosis;" vertebral caries (with a question mark). Report of autopsy: "Carcinoma of the stomach with metastasis to vertebræ; consequent softening of the bodies of two lumbar vertebræ, dislocation, and compression of cord."

Another case. Clinical diagnosis: "Pleurisy." Report of autopsy: "Carcinoma of the stomach with metastasis to liver; some pleuritic effusion at base of lung." It was the lung symptoms evidently that had brought the patient to the hospital. The physical examination had brought out the fact of the presence of effusion which was thought to be much greater in quantity than it was owing to compression of the lung by a cancerous mass of considerable size just below the diaphragm. A third case. Clinical diagnosis: "Anemia from metrorrhagia; extra-uterine pregnancy; death from epistaxis." Report of autopsy: "Universal organic anemia; cystic conditions of both ovaries; adhesions to uterus; peri- and endometritis." All of these patients came to the hospital in the last stages of disease when opportunities for diagnosis were limited and when the hopelessness of the cases awakened little interest in the conditions present. There are good excuses for what are not mistakes but omissions of details in examination. The lesson they teach is an invaluable one, and it is only this perfectly blunt and *cold-blooded* comparison of the clinical with the *post-mortem* findings that can properly bring it out and make it impressive.

The authorities of the city of Moscow, and especially the medical profession, are said to be sparing no effort to make the visitors to the coming international medical congress thoroughly welcome. From St. Petersburg now comes the additional news that special arrangements are to be made there for the entertainment of the foreign attendants upon the congress, most of whom, it is confidently expected, will visit the capital during their Russian trip. The city has just appropriated 5000 rubles (nearly $3000) for the entertainment of medical visitors. A general guide to the city and a special medical guide is to be issued for their benefit. The Court, it is said, is interested in producing a favorable impression on the visitors, and official circles generally will be led by this circumstance to make an effort to have the visit pleasantly remembered by all.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

EPIDEMIC OF INFANTILE PARALYSIS—MALIGNANT STRICTURE OF THE ESOPHAGUS TREATED BY SYMONDS' TUBE—SUCCESSFUL REMOVAL OF A TUMOR OF THE BRAIN—SARCOMA OF THE PROSTATE—HYDATID CYSTS OF THE PLEURA, MESENTERY, AND LIVER SUCCESSFULLY TREATED BY OPERATION—A RECTAL CALCULUS—A NEW ANESTHETIC INHALER.

AT a meeting of the Clinical Society, held March 26th, **PASTEUR** read a paper on *an epidemic of infantile paralysis* limited to the children of one family. Every one of the seven children was attacked within a period of three weeks with fever of moderate severity and intense headache. In three of the children paralysis, not always of the same muscles, followed, within seven days, the beginning of the symptoms. In two others there was no paralysis, but tremors occurred, lasting a few days. In the remaining two cases there were no nervous symptoms.

Diphtheria and influenza were excluded, and a diagnosis of infantile paralysis was made from the points of resemblance to that disease. These cases confirmed the growing impression that infantile paralysis is an acute infective disease.

CAYLÉ said that the cases were clearly instances of an acute specific fever. The term "infantile paralysis" is not always appropriate, and these cases show that anterior "poliomyelitis" is inadequate, since other lesions in the region of the anterior horn may be present. A satisfactory name would greatly stimulate clinical work upon this subject.

LOCKWOOD mentioned a case of *malignant stricture of the esophagus treated with Symonds' tube*, in which the safety-string was swallowed. Every effort to extract the tube failed. As it was not known whether the tube was still in the esophagus, it was decided to perform gastrostomy rather than esophagotomy. The operation gave much relief. The tube was not found, however. Three weeks later the patient died from bronchopneumonia, and the tube was found in the stomach at autopsy.

WASHBOURN and **LANE** described a *successful removal of a tumor of the brain*. The tumor grew from the pia, and deeply indented the brain substance immediately in front of the upper limit of the fissure of Rolando. The tumor was sharply defined, and shelled out easily, although there was a slight attachment to the gray matter at one point. The growth measured 2 by 1.5 inches, and had a depth equal to its breadth. The convolutions depressed by it were the precentral, with the adjacent area of the first frontal and part of the second frontal and marginal convolutions, and probably to some extent the gyrus fornicatus. The operation was followed by aphasia and paralysis of the right arm and right side of the face. The aphasia soon disappeared. Four months later there was complete motor paralysis of the right hand and forearm, with impaired sensation in the fingers. The facial paralysis had disappeared. The patient had been subject to fits before the operation, but there have been none since, and now (six months after operation) movement is returning in the fingers.

At the meeting held April 9th, **MARSH** reported a case of *sarcoma of the prostate*, in which death followed an exploratory operation. The tumor measured seven and one-half by four and one-half inches, and was inclosed in a firm fibrous capsule. It proved to be a spindle-cell sarcoma.

SPENCER described a case in which *hydatid cysts were removed from the left pleural sac, from behind the mesentery, and from the right lobe of the liver.* The pleural cyst was first removed, and, two months after the first operation, an abdominal incision was made, the mesentery cut through, and the cyst, which was situated behind the mesentery, and distinct from the liver, was removed. The wound was closed, and the cyst in the liver reached through an incision in the tenth interspace in the right mid-axillary line. The diaphragm was stitched to the upper edge of the wound, and then incised. The cyst was one and one-half inches within the liver. Fluid shreds and hooklets came away at first through the wound, which gradually healed up. Except in case of the liver, the parasitic cyst was removed without tearing it by passing a stream of water from an irrigator between it and the adventitious cyst after the latter was freely opened.

Spencer pointed out the dangers of aspiration of these cysts; incision being far safer.

At the Pathological Society, April 6th, CRIPPS showed a *concretion removed from the rectum* of a woman, aged sixty-three, who had suffered from almost constant diarrhea, without hemorrhage. The stone weighed nearly eight ounces. Its origin was unknown.

At a meeting of the Society of Anesthetists, held March 18th, HOLIDAY showed *a new anesthetic inhaler*, which consisted of a small bottle with a wide neck, to which was fitted a cork bored for the passage of two tubes. One admitted air to pass over the chloroform, and to take up its vapor, while the other allowed the escape of the mixture of air and vapor. The current of air is kept up by a small bellows, which forces it on toward a mask fitted over the patient's face. Recovery after the use of this inhaler is prompt, and unaccompanied by the nausea which usually follows anesthesia by the open method.

Berlin.

INTERNAL DERANGEMENT OF THE TEMPOROMAXILLARY ARTICULATION—POSSIBILITY OF DISSOLVING URIC-ACID CALCULI.

At the session of the Medical Society, held March 10th, BRUCK presented a girl, aged twenty, who, three months previously, was greatly troubled by a *cracking in the left articulation of the jaw*, coming on not only in chewing, but at every attempt to open the mouth. Accompanying this was a darting pain, and at times an inability to close the mouth. The noise was so loud that she was made sport of by her companions, and fell into the habit of swallowing her food without chewing it, a procedure which speedily caused indigestion and constipation.

Examination showed that if pressure was made with a finger-point upward and inward upon the offending joint, the crack was not heard. It was suggested that the patient wear, during meals, a sort of truss, which should press upon the joint in the manner described, while retaining its own position by a band about the head.

At the session held March 24th, MORDHORST said that he did not share the common belief that there are no efficacious means of dissolving uric-acid calculi. His experience has shown him that every alkalin urine not containing too much of any calcium salt is capable of dissolving uric-acid calculi. The popular belief in the insolubility of these calculi is due to the following facts: If one of these stones is held in a glass of alkalin urine it immediately begins to dissolve. If the urine is very strongly alkalin, the dissolved salts remain in the neighborhood of the stone, and a stroma is formed, visible under the microscope. From the stroma organic substances are dissolved, which unite with the alkali, and form a complete bark, as it were, around the stone, thereby preventing the further action of the alkali upon the uric acid. In other words, the uric-acid calculus is completely surrounded by a layer of urates. If, however, the urine in which the calculus is suspended is frequently changed, these urates will be dissolved, and more and more of the calculus will be exposed to the solvent action of the urine. Exactly the same action may take place in the body. It is immaterial what medicine is employed to make the urine alkalin. Mineral waters taken for this purpose must not contain much calcium, however, because the salts of calcium delay the solution of organic substances. Mordhorst stated, further, that this was not a matter of theory merely, but that in numerous cases he had seen fairly large calculi broken up and voided under the influences of copious draughts of a suitable mineral water.

KUTNER expressed doubt as to the correctness of Mordhorst's explanation of these clinical phenomena. He had had no opportunity to observe them himself, but he expressed himself as convinced that the great increase of urine had mechanically flushed out of the recesses of the pelvis of the kidney, or of the bladder, the calculi which were lodged there, and that the much-wished-for "solution" was by no means proven.

SOCIETY PROCEEDINGS.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Held at Washington, D.C., May 4, 5, and 6, 1897.

SECOND DAY—MAY 5TH.

(Continued from page 654.)

DISCUSSION ON ATROPHIC RHINITIS.

DR. W. E. CASSELBERRY of Chicago opened the discussion, speaking on nature and symptoms. He said that the affection might occur in either the young or old. No one theory of causation was borne out by all cases. The latter were fetid and non-fetid. The atrophy may be due to one and the odor to another. The writer would incline to a division of cases of atrophic rhinitis into (1) simple dry catarrh and (2) ozena, and in a general way the lesions consisted of atrophy in all stages, with possibly a degeneration of the mucous glands and crust formation.

The theory of a primary central trophic neurosis has been advanced. Support is lent to this view by the fact that the disease is generally bilateral. It is true that in case of deviated septum, the affection seems more advanced on the concave side, but as soon as the position of the cartilage is rectified, the nostril improves and the mucosa often assumes a healthy appearance.

In both types the atrophy varies in degree and distribution. Hypertrophy need not exhaust itself before atrophy begins. The middle turbinate may be hypertrophied and the inferior atrophied. Grünwald has claimed that most cases of atrophic rhinitis are due to sinus disease, but this theory has not been generally accepted. Bosworth has referred the disease to a previous suppurative disease of the nasal mucosa. The fetor of these cases has been referred to a microbic origin. Fränkel and Löwenberg have isolated a coccus; Abel has found a bacillus mucosus; Wyatt Winpari, various hyaloid bodies, possibly of a microbic nature; while more recently Belfanti and Della Vedova have found a bacillus closely corresponding to that of diphtheria.

Symptoms frequently include, in addition to those directly referable to the nose, impaired hearing and voice. Ear symptoms may precede the nasal.

The discussion was continued by DR. J. N. MACKENZIE, who spoke of the structural changes occurring in the disease, and the order of their appearance. It must be remembered that we are dealing with changes in an important physiologic organ as well as in a mucous membrane. At present, there is a haze of opinion about the matter. The term atrophy is used in a loose sense. We fail to discriminate between the different forms of atrophy and the different causes producing them. There may be simply atrophy and again one of degeneration. The ideal term is sclerosis, where we may have an atrophy of the specific nasal tissues and a hypertrophy of the surrounding connective tissue. There is a cell infiltration, granulation tissue, obliteration of old and formation of new vessels. Sclerosis may result from blood infection, as from tubercle and syphilis, or from intoxication, especially that of alcohol. Preceding purulent catarrh is probably not a cause, for such a sequence has no known parallel in any pathologic processes with which we are acquainted. The task of the future is to detect the origin of this sclerotic process. The disease may be atropic, *ab initio*, commencing in the periosteum, but this is improbable from the clinical, as well as the anatomic, appearances observed.

DR. C. C. RICE of New York spoke on treatment. This should be constitutional and local. The former would include in the broadest sense the various hygienic measures. He had seen one group of cases improve by removal to the country and the change of occupation from factory to farm. In general, we had to aim at cleanliness and stimulation. The latter might be accomplished by anyone of a number of drugs, by electricity, cataphoresis, tampons, etc. We should be careful to avoid any destruction of tissue. He considered the oily preparations as of great value, both from their power to lubricate and to act as vehicles. The nasal douche cup would carry sufficient fluid for each act of cleansing. He was accustomed to apply the oily preparations by friction, polishing as it were the inside of the nose. In young children with profuse watery secretion powders might be used, not otherwise.

THIRD DAY—MAY 6TH.

SIMULATED SARCOMA OF THE TONSIL; REPORT OF A CASE.

THIS paper was read by DR. D. BRYSON DELAVAN of New York. The tumor grew on the left tonsil of a man aged forty-five, who had a negative family history, and who presented no syphilitic manifestations. The tonsil was moderately enlarged and sore. Its central portion was broken down, leaving a hollowed surface with overhanging edges. The rest of the organ was indurated. There was an enlargement of a gland under the jaw, with pain on palpation and swallowing. The patient was placed on potassium iodid while a bit of the tonsillar tissue was given to Dr. Hodenpyl for examination. Several other pathologists examined it, and pronounced it sarcoma. Dr. Hodenpyl was not sure of the correctness of this view. Under the iodid the glandular enlargement disappeared. The tonsil was removed with a cold snare. The microscopic examination showed chronic hyperplasia, with a large amount of endothelial cell growth, the arrangement of the histologic elements suggesting sarcoma; but after removal the patient did well, and has been in good health since. The case was therefore to be regarded as one of simulated sarcoma.

A NEW METHOD OF PERMANENT RELIEF FOR CERTAIN ENLARGEMENTS OF THE TURBINATED BODIES.

DR. DELAVAN also read a brief paper with this title. He deplored the over-use of the cautery, and thought that much of its employment was futile, as its effects were superficial, and but temporary in duration. The mucosa was also unnecessarily destroyed. He suggested the employment of a small knife, such as is used in eye work. Under cocain the knife may be passed into the turbinated bone, swept around through the tissues, and withdrawn through the same opening, care being taken not to enlarge the latter. It is better to operate a second time rather than to cut too deeply at first. Pain and bleeding are both slight. The latter should be allowed to stop of its own accord. It is also advisable to use cocain freely for some hours after operation.

DR. CASSELBERRY thought that while this procedure would be of service in anterior enlargements, it would not answer when the enlargement was posterior. He alluded to the method of submucous linear cauterization as practised by Dr. Pierce of Chicago.

DR. WRIGHT said, with reference to the case of tonsillar tumor reported by Dr. Delavan, that it was hardly fair to a pathologist to give him only a bit of tissue and expect him always to make a definite and reliable diagnosis. The pathologist should be given all information possible relative to a given case.

A CASE OF SUBGLOTTIC TUMOR CAUSING GREAT DYSPNEA; REMOVAL BY TRACHEOTOMY AND CURETTAGE

was reported by DR. JOHN W. FARLOW of Boston.

The case was that of a woman aged thirty-seven, the history dating back four years. One year after the onset of her trouble she came under the care of a physician in St. Louis, who noted a thickening of the septum nasi. At this time the woman was having so much difficulty in breathing that a tracheotomy was performed. It was found that there was a tumor on the posterior wall of the trachea, pressing on and partially occluding the lumen of the esophagus. It was sessile in character, three-eighths of an inch wide, and one and one-eighth inches long. The color was brown and the consistency soft. Removal was deemed unadvisable, owing to the fear of producing an unmanageable tracheo-esophageal fistula. After the tracheotomy the breathing was greatly improved. She continued well, with only occasional discomfort, until January, 1897, when she came under Dr. Farlow's observation. Her breathing was then difficult and wheezing.

Examination of the larynx showed the cords to be freely movable. The voice was not hoarse. A tumor could be seen filling the trachea below the cords, and presenting the appearance of being made up of several distinct masses. A non-malignant diagnosis was made, the growth being considered an enchondroma. A low tracheotomy was performed, and the trachea opened above the tube. The tumor was found to consist of one mass, with a lobulated superficial division. It was removed with the curette without difficulty, and, on examination, proved to be a fibroma.

PAPILLARY EDEMATOUS NASAL POLYLPI AND THEIR RELATION TO ADENOMATA.

DR. JONATHAN WRIGHT of Brooklyn read a paper with this title.

He reviewed the literature of a series of reported cases, and added notes of some which had come under his own observation. The point made in the paper was that there are a series of intranasal growths which to the unaided eye look exactly like the ordinary polyp and which are in reality quite different. There may be a gradual shading of one into the other so that all grades of transition are seen from the ordinary polyp to the true adenoma.

A CASE OF ADENOCARCINOMA OF THE NOSE.

This paper was read by **DR. F. E. HOPKINS** of Springfield, Mass. The case was that of a man eighty-three years of age whose family had a tuberculous taint but was free from tumors. Nasal obstruction had existed for twelve years with a watery discharge, but no pain or bleeding. A growth was found in the nose and its removal was attempted, but on account of hemorrhage, was abandoned. Shortly afterward some masses resembling polyps were removed. In April of the present year the patient came under the observation of the writer. No operation had been performed during the previous three years. At that time he was troubled with occasional bleeding at the nose and with a constant sanious, foul-smelling discharge. The left eye was displaced outward. The nasal septum had been crowded over to the right side posteriorly. With a cold wire snare, the mass was removed without difficulty. Bleeding was slight. Examination of the tumor showed in some places a tubular and in others an acinous arrangement of cylindrical cells and a few additional irregular cells masses.

DR. SWAIN called attention to the similarity of structure between the ordinary polyp of the ear and the papillary adenomata found in the nose. He believed that the papillary appearance was due to the fibrous tissues as well as to the cell elements.

A CONTRIBUTION TO THE STUDY OF LARYNGEAL PHTHISIS,

was the title of a paper by **DR. T. MORRIS MURRAY** of Washington. The writer had presented a paper on this subject in 1894 and the present communication was a review of the progress made since that time. He spoke of the good effects he had had with enzymol as a digester of necrotic tissue. He believed that the internal use of creosote is of the highest value.

DR. E. FLETCHER INGALS of Chicago said that he preferred the carbonate of creosote to creosote itself. The former could be given in even dram doses and was much better borne by the stomach.

The next paper, entitled

PRIMARY LUPUS OF THE LARYNX

was read by **DR. EMIL MAYER** of New York. He gave the history of two cases occurring in his experience. The first was of a man aged thirty. One week before coming under observation he had coughed up blood, and had had small daily hemorrhages for a week after. Cough, dysphagia, hoarseness, and fever were all absent. Examination showed the entire surface of the laryngeal aspect of the epiglottis to be ulcerated. The edges of the ulcer were granular and were covered with a whitish deposit with numerous small nodules on the free edge. The deepest point of ulceration presented an erosion like the open mouth of a small vessel. The arytenoids were normal. There were no bacilli in the sputum. There was no evidence of syphilis, but there was a small spot of consolidation at the apex of the left lung.

Under lactic acid applications, with menthol, and the use of creosote internally, the patient improved rapidly, the hemorrhage never returning after the third day. Ten months later, it was found that the epiglottis was thickened, with a nodular excavation in its central portion. In addition, the mucous membrane of the epiglottis adjacent to the ulcer, was puffy and edematous. The edematous folds hung like pouches over the larynx, obscuring its interior. The lung condition was about the same as when first noted.

Primary lupus of the larynx, while rare, undoubtedly does occur. Fourteen other cases have been reported. The condition must be differentiated from tuberculosis, syphilis, carcinoma, and leprosy.

The reader of the paper drew the following conclusions: (1) Primary lupus of the larynx does exist. (2) It is a painless affection and may go on for years unnoticed. (3) Tubercle bacilli are present in small numbers, although difficult to find. (4) Its similarity to syphilis in appearance is greater than that of tuberculosis. (5) The absence of adhesive bands is characteristic of lupus, while always present in late syphilis. (6) The prognosis as to life is remarkably good.

FOUR CASES OF SARCOMA OF THE NASAL CAVITIES

were reported by **DR. J. E. H. NICHOLS** of New York.

Several papers were then read by title.

DR. JOHN O. ROE of Rochester exhibited an instrument for dilating the trachea in cases of stenosis.

The following were elected to active membership; J. Payson Clark, M.D., Boston, Thesis, "Nasal Polypi"; J. Edwin Rhodes, M.D., Chicago, Thesis, "Atrophic Rhinitis"; James E. Logan, M.D., Kansas City, Thesis, "Laryngitis Rheumatica, with Report of a Case"; Richard Frothingham, M.D., New York, Thesis, "Benign Retropharyngeal Tumors, with Report of Cases." H. Luc, M.D., of France, Paris, was elected to corresponding fellowship.

The annual election of officers resulted as follows:

President, Thomas R. French, M.D., of Brooklyn; first vice-president, Alex. W. McCoy, M.D., of Philadelphia; second vice-president, Herbert S. Birkett, M.D., of Montreal; secretary and treasurer, Henry L. Swain, M.D., of New Haven; librarian, J. H. Bryan, M.D., of Washington.

It was voted to hold the next Congress in Brooklyn, the date to be selected by the Council.

AMERICAN PEDIATRIC SOCIETY.

Ninth Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

THE first session was opened by the President, DR. SAMUEL S. ADAMS of Washington, who delivered an address entitled "The Evolution of Pediatric Literature in the United States." In this address he reviewed, in chronologic order, the various works on the diseases of children which have been written in this country during the past one hundred years. Every author writing upon this subject before 1870 was mentioned. Since that date the contributions have been too numerous to receive individual mention. The first definite contribution to pediatric literature was made by Dr. Rush in 1789, in a description of influenza. Following this were mentioned the names of Caldwell, 1796; Steuart, 1806; *The American Matron*. 1810; Jackson, 1812; Miller, 1814, and Logan, 1825. There were numerous contributions between the last-named date and 1848, when J. Forsyth Meigs published his important work on the "Diseases of Children," the last two editions of which appeared under the authorship of Meigs and Pepper. The next important name in pediatrics appeared ten years later, when Jacobi wrote his first paper on children. It is also notable that J. Lewis Smith wrote his first paper on children in the same year. The first edition of his well-known work on diseases of children appeared in 1869. The most important works that have since appeared on this subject are those of Keating, in 1889; Starr, in 1894; Sachs, 1895; Rotch, 1895, and Holt, 1896.

DR. JAMES C. WILSON read a paper on "Tic Convulsif," and reported a case which belonged to the class of nervous diseases which includes the "jumpers," described by Beard.

DR. B. SCHARLAU presented a synopsis of fifty-six cases of empyema operated upon during 1896 with very favorable results.

DR. W. D. BOOKER reported a case of congenital diaphragmatic hernia associated with recurrent attacks of asthma dyspepticum. During one of these attacks the child died, and the true pathologic conditions were revealed by the autopsy.

DR. J. P. CROZER GRIFFITH reported two cases of unilateral tremor in children.

DR. J. HENRY FRUITNIGHT read a paper on the "Frequent Significance of Epistaxis in Children."

He believed that this symptom was frequently the result of cardiac disease, and should always receive full attention.

DR. GEORGE N. ACKER reported two cases of meningitis, apparently tuberculous in nature, with recovery.

DR. JOSEPH O'DWYER reported a case of congenital stenosis of the larynx, in which relief was obtained by gradual dilatation with steel sounds.

DR. WILLIAM OSLER read an extended paper on "Adherent Pericardium in Children," and reported cases.

DR. A. JACOBI reported a case of sarcoma of the skin in a newly born infant, and read a paper on the origin of such growths.

DR. F. GORDON MORRILL reported an analysis of one hundred cases of frank pneumonia, that term being used rather than lobar pneumonia, because of the confusion caused by the use of the latter term when applied to the pneumonias of children.

DR. FLOYD M. CRANDALL read a paper on "Hereditary Tendency in Pediatric Practice," and called particular attention to certain misapprehensions which sometimes arise regarding that subject.

DR. B. K. RATCHFORD read a paper on the "Symptoms of Lithemia as they Appear in Children," and considered the special symptoms in detail.

In a paper on "Retro-esophageal Abscess," DR. J. P. CROZER GRIFFITH called particular attention to the great difficulties experienced in making a diagnosis of that condition.

DR. C. G. KERLEY reported a case of exophthalmic goiter apparently cured by the use of thyroid extract. The case was an undoubted one, and the beneficial effects of the extract seemed to be equally clear.

DR. HENRY KOPLIK reported the extensive use of thyroid extract for the purpose of testing its value in different diseases of the blood and bones, and his conclusions suggested its more general use in these diseases.

DR. FRANCIS HUBER also presented a paper reporting "A Cure of Goiter by Thyroid Extract."

The report of the Committee on

THE COLLECTIVE INVESTIGATION OF THE ANTITOXIN TREATMENT OF LARYNGEAL DIPHTHERIA IN PRIVATE PRACTICE

was read by the Chairman, DR. W. P. NORTHRUP, the conclusions being as follows: (1) The mortality of laryngeal diphtheria at present rests at 21.12 per cent.; (2) that sixty per cent., approximately, have not required intubation; (3) that the mortality of operated cases is at present 27.24 per cent.

DR. JOSEPH O'DWYER read an important paper on "Retained Intubation Tubes," this term being used to mean the necessity of continuing intubation long after the disappearance of the original disease.

DR. T. M. ROTCH reported cases of diphtheria of the eye and discussed the subject of antitoxin in diphtheria.

DR. HENRY KOPLIK exhibited an apparatus by which the bacteriologic diagnosis of diphtheria could be made within three or four hours.

DR. EDWARD P. DAVIS presented an important contribution on "Prenatal Infection in Infancy," causing diseases which develop during the first month of life.

DR. IRVING M. SNOW reported a case in which poisoning by acetanlid had resulted from the absorption of that drug in the umbilical wound.

DR. T. M. ROTCH presented a specimen of iliocolitis, and Dr. R. G. Freeman presented an improved nursing bottle.

Papers were read by title by Drs. J. Lewis Smith, W. F. Lockwood, W. P. Northrup, R. G. Freeman, H. D. Chapin, Francis Huber, C. G. Jennings, and C. P. Putnam.

The following officers were elected for the ensuing year: President, Dr. L, Emmett Holt; first vice-president, Dr. Henry Koplik ; second vice-president, Dr. Charles G. Jennings; secretary, Dr. Samuel S. Adams, recorder, Dr. Floyd M. Crandall; treasurer, Dr. F. A. Packard; member of Council, Dr. Charles P. Putnam.

The following were elected members: Dr. J. H. McCollom, Boston; Dr. J. P. West, Bellaire; Dr. Churchill, Chicago; Dr. E. E. Graham, Philadelphia; Dr. Harold Williams, Boston.

The subject of infantile scorbutus was selected for collective investigation, the report to be made at the next meeting. The following committee was appointed: Drs. W. D. Booker, J. P. Crozer Griffith, C. G. Jennings, A. Caillé, and J. Lovett Morse.

Cincinnati was named as the next place of meeting, the exact date of which was not decided.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Thirty-third Annual Meeting, Held at Washington, D. C., May 5 and 6, 1897.

First Day—May 5th.

The President, Dr. George C. Harlan of Philadelphia, in the Chair.

Dr. J. A. Spalding of Portland, Me., read a paper on

ENUCLEATION OF BOTH EYES, OWING TO PANOPHTHALMITIS, IN A CASE OF EXOPHTHALMIC GOITER.

Dr. W. F. Aiken of Savannah reported a case of exophthalmic goiter in which the eye first became prominent after etherization for a surgical operation. The case gradually improved for two years. Vision continued normal.

Dr. W. H. Wilder reported three cases of pulsating exophthalmus—the first his own, the second in the service of Dr. Ralph Isham, and the third Dr. Beard's case. His conclusion was that ligature of the common carotid gives the best result.

Dr. S. M. Burnett of Washington, D. C., reported a case of double exophthalmus, with destruction of eyes, in an infant, starting probably from the dura near the cella turcica, with exhibition of the specimen, which he considered a sarcoma strictly localized.

Dr. J. O. Tansley of New York spoke of having seen a number of cases of exophthalmus, and quoted briefly from two.

Dr. Lucien Howe of Buffalo, N. Y., exhibited a case of

CHRONIC PSEUDO-MEMBRANOUS CONJUNCTIVITIS,

and remarked upon its pathology and the difficulties in the way of treatment.

Dr. Myles Standish of Boston read a paper on

DIPHTHERITIC CONJUNCTIVITIS.

He had seen rapid and permanent benefit from injections of antitoxin, and believed it advisable to repeat the injection as often as necessary to keep up the improvement.

Drs. G. E. de Schweinitz of Philadelphia and John E. Weeks of New York spoke in confirmation of the conclusions of Dr. Standish.

Dr. Geo. C. Harlan reported a new operation for prothesis in cases of cicatricial orbit, showing photographs and specimens of lead wire and shell used in the procedure.

Dr. W. F. Norris of Philadelphia reported a case of ivory exostosis of the orbit, and Dr. Robert Sattler of Cincinnati presented a supplementary report of a case previously related to the Society.

Dr. Edward Jackson of Philadelphia reported a case of unique intra-ocular tumor, characterized by rapidity of onset, inability to close one eye without closing the other, and rapid loss of vision. Diagnosis before operation, sarcoma of choroid; after enucleation, tumor was found, partly of the consistence of bone.

Dr. W. B. Johnson of Paterson reported a case of angiosarcoma, of probably retinal orgin, with specimen mounted in gelatin, which Dr. Weeks thought should be called angioglioma.

Dr. William Thomson reported two cases—one of a foreign body in the lens, which was removed entire in its capsule, and the resulting vision was $\frac{20}{40}$; and after a blow on the eye, which reopened the wound, the final result was V-$\frac{1}{3}$. In the second case, the foreign body was located by means of radiographs and a system of triangulation, in a fibrous band extending forward from the retina; an opening was made and a piece of the band containing the encapsulated foreign body removed.

Dr. Wm. M. Sweet of Philadelphia demonstrated the method of triangulation used. Dr. C. A. Oliver demonstrated a method of triangulation, which he regarded as more practical than that of Exner.

The Society then went into executive session.

Second Day—May 6th.

The second session was opened at nine o'clock with the relation of

THE REMOVAL OF AN EPITHELIOMA OF THE LOWER LID,

by Dr. C. H. Williams of Chicago, Ill., the interesting feature being the production of anesthesia by cocain cataphoresis.

Dr. Robert Sattler related a case of congenital ptosis and epicanthus with operation and photographic exhibit, showing other members of the family affected.

Dr. W. H. Wilder reported a new operation for ptosis, stating the objections to the operation of Panas. His own operation consisted in a folding of the tarso-orbital fascia and getting a hold on the occipito-frontalis muscle, which leaves the orbicularis uninjured. Dr. C. A. Oliver reported two cases of resection and advancement of the levator-palpebræ muscle in traumatic ptosis, with blackboard demonstration.

Dr. G. M. Gould of Philadelphia, Pa., read a paper on the

LAW OF REFRACTION—CHANGE FOLLOWING INCREASE OR DECREASE IN BODY-WEIGHT.

(To appear shortly in the MEDICAL NEWS.)

DR. WILLIAM THOMSON exhibited an achromatic cataract lens, made by Bausch, with the main glass of crown glass, the added portion flint glass, with remarks upon its clearness of definition. DR. S. D. RISLEY of Philadelphia related two cases of saccharin diabetes, accompanied by refractive changes varying with the changes in the general condition of the patient. When the sugar disappeared the hypermetropia increased, and when it reappeared the hypermetropia diminished.

DR. E. FRIDENBERG of New York thought that the changes noticed by Dr. Risley were perhaps due to changes in the index of refraction of the media, and that the cases of Dr. Gould might be partially explained in the same way. DR. S. THEOBALD thought that perhaps some of Dr. Gould's cases might be explained by the measurements, possibly representing more than the true amount of myopia, and less than the true amount of astigmatism.

DR. GOULD, in closing the discussion, stated that in the cases quoted the ciliary muscle had been paralyzed by a mydriatic, but DR. THEOBALD thought that a mydriatic might not always entirely eliminate action of the ciliary muscles.

DR. R. L. RANDOLPH reported a second series of cataract extractions, numbering 147, of which in 107 an iridectomy was made, and 42 were simple extractions. He found the failures not due to prolapse, but to simple iritis, as in cases where iridectomy had been performed.

DR. O. F. WADSWORTH of Boston, Mass., reported

CASES OF INTRA-OCULAR HEMORRHAGE DURING AND FOLLOWING CATARACT EXTRACTION.

In the first case, after the section, a stream of blood flowed from behind and below the iris over the lens, followed by prolapse of iris, ending in atrophy of eyeball. Second case, section as usual with similar result, the blood forcing the corneal flap to fold over. In the third, a case of simple extraction, prolapse of iris occurred, followed by blood. Eye enucleated. This patient died of apoplexy a year later. In the fourth case, fifteen minutes after operation, there was prolapse of iris and vitreous. The fifth case was an American woman in good, general health and with good projection. After the removal of the lens, there was sudden pain, protrusion of vitreous, followed by blood.

DR. L. A. W. ALLEMAN of Brooklyn, N. Y., reported a case of cholesterin crystrals in the opaque lens of a child. The lens was needled, and as much as possible removed by suction.

DR. S. B. ST. JOHN of Hartford, Conn., wished to emphasize the practicability of cataract extraction without expert assistance. In doing iridectomy he put cocain into the anterior chamber and waited a minute or two, when the iris was cut with no pain.

DR. DAVID WEBSTER of New York reported a case of cataract extraction, with intra-ocular hemorrhage and protrusion of vitreous, retina, and he thought choroid. He enucleated the eye a few days later.

DR. S. O. RICHEY of Washington, D. C., read a short paper on

TAXIS IN INCREASED INTRA-OCULAR TENSION.

He referred to the position of the venæ vorticosæ in their passage through the sclera, and suggested the transfer of attention from the anterior to the posterior segment of the eyeball.

DR. G. E. DE SCHWEINITZ of Philadelphia, Pa., related a case of tobacco amblyopia, with autopsy and microscopic examination of the specimens, showing the nerve bundles affected, and DR. S. THEOBALD related a case of marked impairment of central vision following prolonged use of the affected eye in calibrating burettes, with paracentral scotoma. Treatment was pilocarpin, followed by mercuric biniodid, with a result of V-$\frac{20}{20}$.

DR. J. A. SPALDING of Portland, Me., reported a group of four cases of optic-nerve atrophy following sexual excess. The results were gradual loss of useful vision, though not total blindness. Two became victims of phthisis, the third was committed to an insane asylum, and the fourth committed suicide.

AMERICAN DERMATOLOGICAL ASSOCIATON.

Twenty-first Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

FIRST, SECOND, AND THIRD DAYS.

THE proceedings were opened with an address by the President, DR. JAMES C. WHITE of Boston. He reviewed the work of the Association in connection with the many advances in dermatology, and said that the amount of data gathered during the twenty-years' existence of the Association was of inestimable value. In addition to the numerous systems, treatises, atlases, etc., published by the members, 327 papers of value had been contributed to the Association, and the journal devoted to this special branch had reflected great credit upon its various editors. American dermatologists might well feel a sense of satisfaction in the part they had taken in separating and classifying various confused groups of disease, and the future of the Association seemed very bright.

A CONTRIBUTION TO THE STUDY OF BLEEDING STIGMATA

was the title of a paper presented by DR. J. N. HYDE of Chicago.

A peculiar and seemingly unique instance of spontaneous bleeding from the skin was related as having occurred in a male subject. In spite of his residence in a healthy, non-malarial district, the plasmoidium was repeatedly discovered in the blood, though neither the spleen or liver was enlarged. The bleeding was from a single point at a time, and continued as long as six months during one attack. There was no hemorrhage from any mucous membrane.

HYSTERICAL DERMATONEUROSES

was the title of the next paper, which was read by DR. VAN HARLINGEN of Philadelphia. Four cases of his own were reported, and three occurring in the practice of others were mentioned. They all concerned young girls, some of whom were hysterical, and for the most part anemic. In one woman crops of bullous lesions were present, which continued over a period of two years. In one young girl three attacks followed her being sent to school against her will, and a fourth was called forth by the mere mention of school. They subsided upon the patient being kept at home. The speaker thought all these reported instances were due to a definite process, and that we are warranted in supposing an internal cause of the malady to be present. The title "neurotic excoriation" was not sufficiently exact to be retained; hysteria was looked upon as the condition upon which the cutaneous lesions depended.

Many lesions undoubtedly appear as though self-inflicted, although the term "feigned" cannot apply to them.

LINEAR NEVUS

was discussed from the standpoint of etiology and pathology by Dr. P. A. Morrow of New York. Of the many names proposed for this affection, he had chosen the one he thought best suited for it. He would drop the qualitative term neuropathic as unwarranted. He reported two instances, one affecting the side of the neck and back in a young woman, the other running down the arm and over the palm to the tip of one of the fingers in a man. He thought there were diverse clinical varieties of this wart-like nevus, and that while not strictly limited to one side of the body, nor to any particular nerve distribution, the affection bears a close analogy to zoster, which is now known to be of nerve origin.

The histologic examination of his cases had shown the changes habitually noted in this affection. Both instances reported had developed long after childhood, and had existed twelve and seven years, respectively.

THE VARIOUS FORMS OF PITYRIASIS AND THEIR RELATION TO ERYTHEMA, ECZEMA, AND PSORIASIS

was the title of a paper by Dr. George H. Fox of New York. The contention was made that seborrhea, as such, had no place in modern nomenclature; that the pityriasis group includes, or should include, many scaly or oily affections known under various other names. It was thought that some simple term to correspond to "acne" "eczema," and "psoriasis" would do away with much present confusion. The term pityriasis, he thought, would cover many conditions of skin lesion now grouped elsewhere, and to illustrate this point a series of prints were exhibited showing the great resemblance between them, as well as between this whole class of affections and psoriasis. Pityriasis rosa had been included by Dr. Fox in the scaly affections which he would class together. This had given rise to almost unanimous opposition, since it was claimed that this affection stands out by itself with distinctive features, and can be readily diagnosticated at a glance in almost every instance.

It was admitted that many clinical symptoms seem to merge and confuse, but efforts should be directed toward differentiation of similar, but still distinct, diseases, instead of taking a step backward, as it would seem to be, in grouping them together. One point made was that seborrheal affections are persistent, while pityriasis rosa is evanescent.

Dr. Duhring said he recognized several of this class of affections as distinct. There was (1) pityriasis rosa, of which there may be an acute and a chronic form, the latter lasting as long as a year. These may or may not recur. (2) Seborrhea, which may attack any region of the body. (3) An eczema, which may be complicated by seborrhea, and for which the term "eczema seborrhoicum" may be retained. Other diseases may simulate these. The term pityriasis, as proposed by Dr. Fox, must be more clearly defined before it can be accepted to cover the group of affections as proposed.

Dr. H. G. Klotz read a paper, entitled

STRONG APPLICATIONS OF THE ICHTHYOL GROUP.

He found that in acute inflammatory states, as well as in more chronic processes, a judicious use of strong solutions is often of much benefit. Stress was laid upon the contracting power over the vessels exerted by ichthyol, especially in erysipelas. To this, no less than to the antiseptic qualities of the drug, is due its favorable action. It is very useful in ivy poisoning, dermatitis, and a variety of other acute inflammations, including the dermatitis caused by burns, freezing, scratching; in intertrigo eczema, zoster, and the erythemata. In chronic processes and inflammations the effects are still more marked. It is usually not necessary to combine any varnish or collodion with the drug, since it forms in itself a sufficient protective.

A paper, entitled

A CONTRIBUTION TO THE ETIOLOGY OF CONGENITAL ICHTHYOSIS, WITH ABSENCE OF THE THYROID,

was read by Dr. James M. Winfield.

After giving the family history, the paper entered into the history of the mother. She had been pregnant seven times, four children being normal and two ichthyotic. During the first, second, third, fourth, and sixth pregnancies the mother's condition was excellent. During the fifth, which resulted in the first ichthyotic infant, she was subjected to considerable anxiety, and at the sixth month received a severe nervous shock. When she became pregnant for the last time, she immediately grew exceedingly nervous and worried lest she should become the mother of another deformed baby. At delivery the infant weighed four pounds. The body was enveloped in what appeared to be a thick coating of vernix caseosa, which, on removal, left the skin red and shiny. If no lubricating protective was used, the whole cutaneous surface soon became scaly and fissured. Four days after delivery the infant appeared as follows: The whole body was covered with thick, reddish-brown, epidermic plates, which were larger and more marked over the extensor surfaces; some of them were from a sixteenth to a tenth of an inch in thickness, and a half to two inches in diameter. Between the plates were fissures of varying depths. Movement of the limbs produced cracks about the flexures of the joints, which extended deeply into the underlying tissues.

The autopsy was made about eight hours after death.

The body was considerably emaciated and covered with large, fatty, epidermic scales. On examining the neck, the thyroid gland was found to be absent. There was no sign or trace of its ever having existed.

The important etiological points are: (1) the absence of the thyroid gland; (2) the presence of micro-organisms in and about the lymph spaces.

Just what etiological bearing the absence of the thyroid has on the production of ichthyosis congenita and kindred diseases cannot be positively stated without further clinical and *post-mortem* study. Still, from the above facts, it is but fair to conclude that, in this case at least, the absence of this gland had some marked effect on the nutrition of the skin and the development of the cutaneous affection.

The occurrence of micro-organisms in the lymph spaces at once brings up the question whether this and similar cases are types of true ichthyosis or, as Dr. Van Cott puts it, a variety of dematitis.

If these micro-organisms were the cause of this excessive plate formation, it is possible that the term ichthyosis sebaceæ is the correct one, for a bacterial irritation could easily produce a universal seborrhea.

HEREDITARY AND CONTINUOUS SHEDDING OF THE FINGER-NAILS

was the title of a paper presented by DR. D. W. MONTGOMERY of San Francisco.

A case was described in which, without evidence of disease of the nail itself, this appendage was thrown off at longer or shorter intervals during the subject's whole life. His mother and an uncle on her side had been similarly affected. The nail began to loosen in the region of the matrix, the loosening process gradually extending forward toward the free border. Corresponding nails upon the opposite side would be simultaneously affected, and after an interval the remaining nails would follow in the same manner. It was the only case in literature, so far as the reader knew, where such continuous loss of nails had occurred.

SYMMETRICAL ATROPHY OF THE SKIN; REPORT OF A CASE, WITH COLORED DRAWINGS AND PHOTO-MICROGRAPHS.

DR. J. A. FORDYCE of New York City reported such a case which occurred in a woman aged forty years. The hands, elbows, knees, and ankles were the seat of atrophic lesions, which were surrounded by a dusky red zone of dilated capillaries. The atrophy followed closely on the hyperemia, which seemed to be the primary condition. Clinically, the affection resembled the cases described by Buchwald, Pospelow, Touton, Bronson, and others. The eruption was absolutely symmetrical and had, up to a short time before, been progressive. On microscopic examination, the atrophy was found to be secondary to an inflammation which was located in the skin and underlying connective tissue. The epidermis was invaded by exudation corpuscles, which had produced a thinning and degeneration of the constituent cells. No organic affection of the nervous system could be detected, although there was evidence of vasomotor disturbance.

A PECULIAR AFFECTION OF THE HAIR-FOLLICLE

was the title of a paper read by DR. JOSEPH GRINDON of St. Louis.

The affection consists of a chronic inflammation of the hair-follicle, characterized by extrusion of a portion of the root sheath proper *en masse*, which remains threaded over the hair and is carried up with it in its growth, the process being repeated from time to time until successive masses bearing a superficial resemblance to nits are strung along the hair. It is accompanied by slight redness about the mouth of the follicle, and results in a curable alopecia.

There are found little grayish-white masses threaded beadwise on the hair. In their size, color, and distribution they are so like the ova of the pediculous capitis that one is almost certain to mistake them for the latter at first sight.

The little masses consist of the cells of both layers of the internal root sheath surrounded by a layer of amorphous detritus and sebum.

DR. ALLEN presented

A SCALE OF MEASUREMENTS FOR THE ACCURATE AND UNIFORM DESCRIPTION OF CUTANEOUS LESIONS, OF UNIVERSAL ADAPTABILITY.

He thought the desirability of a uniform system of description which might be followed by dermatologists in all countries need not be dwelt upon.

The unit upon which this scale is drawn is one-quarter of a millimeter. Five hundred is the largest size shown on the scale, but larger plaques, tumors, etc., may be readily described in multiples of this diameter. The scale numbers can be reduced to millimeters if desired by dividing by four. Thus, No. 40 is ten millimeters, or one centimeter in diameter. The term *tetmil* is proposed to designate the unit. It is especially in the smaller sizes that accuracy is often of the utmost importance in describing the primary lesions of a disease.

The method now employed to denote the relative size of lesions is too inaccurate, unsatisfactory, and unscientific. After discussion, it was voted to refer the subject to the committee on nomenclature. It was also decided that the Association should present a scheme such as that proposed at the coming International Dermatological Congress.

The meeting then adjourned to meet in or near New York City on the first Tuesday in June, 1898.

The officers elected for the ensuing year were: J. N. Hyde of Chicago, president; E. B. Bronson of New York, vice-president; J. T. Bowen of Boston, secretary.

AMERICAN OTOLOGICAL SOCIETY.

Thirtieth Annual Meeting, Held at Washington, D. C., May 4, 1897.

The President, DR. ARTHUR MATHEWSON of Brooklyn, in the Chair.

AFTER the disposal of the usual executive business DR. A. H. BUCK of New York opened the scientific proceedings by reading a paper on

GOUTINESS IN ITS RELATIONS TO DISEASES OF THE EAR.

After directing attention to the absence of references in literature to this subject, Dr. Buck expressed the opinion that gout would be found to be a more considerable factor in a certain class of affections of the ear, than had hitherto been suspected. He spoke of the ease with which spontaneous stagnation of the blood current could occur in parts of the auditory apparatus, as favorable to the interference of uric-acid irritation, and illustrated the subject by the introduction of the history of several cases calculated to show the vicious circle which can only be broken by measures addressed to the general condition. The paper received marked attention, and the discussion brought out only one or two differences of opinion on minor details.

DR. E. B. DENCH'S paper on

THE DIFFERENTIAL DIAGNOSIS BETWEEN DISEASES OF THE SOUND-CONDUCTING AND SOUND-PERCEIVING APPARATUS,

stated that physical inspection of the ear cannot be relied upon to show the state of the hearing. He divided the affections of the hearing into two parts, those dependent upon interference (1) with the conducting and (2) with the perceiving apparatus. Quantitative audition is determined by noises, while qualitative audition is measured by musical tones. A description of the results obtained by the use of the tuning forks was followed by the statement that in disease of the conducting apparatus the lower tones are always lost first, while in affections of the sound-perceiving apparatus the lower tones are not lost. In conducting defect the high tones are good whereas in perceptive difficulty they are lost. An explanation of the reason why this should be so followed. In disease of the sound-conducting apparatus bone conduction is always exaggerated, but in mixed cases where the impairment is extreme air conduction is better than bone except for the very lowest notes.

The discussion of the paper was participated in by DRS. S. THEOBALD of Baltimore and H. A. ALDERTON of Brooklyn who had been puzzled by the varying results obtained with the tuning forks on the vertex and on the mastoid ; and by DR. CLARENCE J. BLAKE of Boston, who explained that the variations complained of were doubtless due to varying thicknesses of the skull at different points even in the same subject.

DR. W. P. EAGLETON of Newark read a short paper on

EAR COMPLICATIONS OF INFLUENZA,

and gave statistics showing the relative virulency. This was followed by one by DR. GORHAM BACON of New York on

IMPORTANT SYMPTOMS INDICATING OPERATION IN MASTOID DISEASE.

He had never seen a case without some elevation of temperature, but the temperature may range lower in adults than in children. High temperature is not necessarily indicative of extensive disease. In determining tenderness, pressure should always be made over the fellow mastoid for comparison. Redness and edema over the mastoid are not so necessary and not to be waited for. Bulging of Shrapnell's membrane is always an indication for opening the mastoid cells. Sometimes the temperature remains high after operation.

DRS. W. B. JOHNSON of Paterson, DENCH and J. O. TANSLEY of New York participated in the discussion which followed. The opinion was advanced that the continued high temperature after operation may be due to infection of the newly incised and exposed surfaces ; differences of opinion developed as to whether inflation after incision of the membrane in acute cases was dangerous or the reverse. Dr. Bacon only politzerizes when the inflammation has practically subsided and there is a free opening in the membrane.

DR. H. A. ALDERTON of Brooklyn, in a paper on

A CASE OF THROMBOSIS OF THE LATERAL SINUS,

accompanied by a specimen, raised the question as to the advisability of ligating the jugular to prevent extension of the septic condition. One point of interest in the case reported is that the sinus was in front of the antrum, and when evacuated of débris temporary improvement occurred, but a day later metastatic pneumonia set in with death four or five days later.

DRS. DENCH and BACON did not think it always necessary or advisable to ligate the jugular vein, and thought that in many cases the extension of the sepsis was arrested as soon as the septic material and thrombus was removed.

DR. GORHAM BACON related the details of a case of extreme deafness in which great improvement of hearing followed the use of pilocarpin hypodermatically, and expressed the opinion that the want of success in many cases may be due to the shortness of the period of treatment.

DR. TANSLEY suggested that the length of treatment was an obstacle in some cases, and thought as good results had been achieved when administered by the mouth. Other speakers concurred with Dr. Bacon in thinking that pilocarpin by the stomach had not shown anything like the happy results obtained hypodermatically.

DR. J. OSCROFT TANSLEY described

A NEW OPERATION FOR DEVIATED SEPTUM,

which consisted in converting the septum into a spur by folding it upon itself, then at a second sitting ten days later removing the spur.

DR. ROBERT C. MYLES of New York read a short paper on

CICATRICIAL BANDS IN THE NEIGHBORHOOD OF THE FOSSA OF ROSENMULLER, SIMULATING STENOSIS OF THE EUSTACHIAN TUBE,

which he had found easy to remedy by breaking up the bands with the finger, resulting in immediate improvement in hearing.

DR. J. E. H. NICHOLS exhibited an electric speculum with head band, operated by storage battery, which gave perfect light to the ear and left both hands free for manipulations.

REVIEWS.

A SYSTEM OF PRACTICAL MEDICINE. By American authors. Edited by ALFRED LEE LOOMIS, M.D., LL.D., late Professor of Pathology and Practical Medicine in the New York University, and WILLIAM GILMAN THOMPSON, M.D., Professor of Materia Medica, Therapeutics, and Clinical Medicine in the New York University; Physician to the Presbyterian and Bellevue Hospitals, New York. Volume I. *Infectious Diseases.* New York and Philadelphia: Lea Brothers & Co., 1897.

IT is unfortunate that the late Dr. Loomis could not live to see the publication of this work on which he had long been engaged and which, in many respects, will form one of the best systems of medicine published in this country. There certainly must be an active demand for collaborative works of this nature, for the last two years has seen the appearance of several systems devoted to internal medicine. It is not saying too much to express the belief that the one under consideration will at once assume a rank at once gratifying to the publishers and the authors.

The present volume on the infectious diseases is scientific, complete, and direct. The articles do not possess, however, a character so deep, no reasoning so abstruse, that their reading is burdensome. All of the chapters are written by men whose verdicts are regarded as authoritative, and their dicta may, therefore, be accepted as conclusive. It is of great value, too, to know that statements are made with some show of authority, and that they are based upon actual knowledge and experience rather than upon a collection of facts from literature with a verdict wavering with each author cited.

It is almost impossible to review critically each of the articles in this volume. Every chapter contains an historical account of the disease with which it deals, followed by the etiology, the morbid anatomy, the differential diagnosis, diagnosis, complications, the prognosis, and the treatment. The practical value of the work is much enhanced by the attention given to the consideration of the diagnosis, differential diagnosis, and treatment, Thus twenty-four pages are devoted to the treatment of typhoid fever, and twenty-eight to the treatment of diphtheria, including an exhaustive account of the antitoxin results. The author, by the way, praises the use of the antitoxin serum.

All of the chapters, it has been said, have been written by most competent observers. It would, therefore, be unjust to institute comparisons. Yet the chapters on malaria, yellow fever, typhoid fever, tuberculosis, and erysipelas seem to us to be particularly well conceived. Unless it be Monnaberg's or Thayer and Hewetson's monograph, we know of no clearer, more complete, and more logical exposition of the subject of malaria than is contained in this volume. Although the articles mentioned seem to bear the stamp of authority perhaps more markedly than some of the others, the implication of inferiority is by no means intended. The volume stands as a model of literary and scientific excellence, and we expect, therefore, to see it occupy the prominence it deserves among the books of the year. It is reasonable to infer that the succeeding volumes will have as high a standard.

The proof-reading and editing are above reproach. The book is handsomely printed on heavy paper, is splendidly illustrated, and is excellent in the style and color of its binding.

THE YEAR-BOOK OF TREATMENT FOR 1897: A Critical Review for Practitioners of Medicine and Surgery. Philadelphia and New York: Lea Brothers & Co., 1897.

THIS year-book is so widely known as to require merely the announcement of its publication for the current year. Its twenty-six contributors are mainly specialists whose critical examination of the literature of the past year makes the work of the greatest value to one whose desire is to keep abreast of what is being accomplished in the ever-widening fields of medicine. All the advances made in the last year in the provinces of medicine and surgery are here faithfully recorded and reviewed by critical experts, and the present volume will, we are sure, reach the same measure of success as its predecessors.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. For the use of Students and Practitioners. By J. NEVINS HYDE, A.M., M.D., Professor of Dermatology and Venereal Diseases in Rush Medical College, Chicago, and FRANK H. MONTGOMERY, M.D., Lecturer on Dermatology and Venereal Diseases, Rush Medical College, Chicago. New (fourth) edition. In one octavo volume of 815 pages, with 110 engravings and 12 full-page plates, 4 of which are colored. Cloth, $5.25; leather, $6.25. Philadelphia and New York: Lea Brothers & Co., Publishers.

"GOOD wine needs no bush"; no more does a book in its fourth edition need the commendation of the reviewer, for the great public has already passed its verdict. In the present instance the author and his publishers deserve congratulations upon the success achieved, for the work of both has been most excellently done and is in every way reliable and satisfactory.

The new chapters contained in this fourth edition are a valuable addition, and not a few of those with which we were familiar have been entirely rewritten and brought up to date. Among the former are included chapters on Conglomerate Pustular Perifolliculitis, Dermatitis, Seborrhoicum, Epidermolysis Bullosa Hereditaria, Erysipeloid, Erythema Induratum, Hidradenitis Suppurativa, Hydrocystoma, and Lichenification, but we have failed to find mention made of Baelzer's Disease, Cheilitis, Glandularis, or Porokeratosis. Several new plates and wood-cuts have been added. We note also that the simplified system of spelling has been adopted, as in nevus, hyperesthesia, myxedema, and the like, but the convictions of the orthographer have not given him courage to follow the same plan with reference to edema.

As has been said, the book is thoroughly deserving of its success, and there can be no doubt that it will pass through many succeeding editions.

A MANUAL OF VENEREAL DISEASES. By JAMES R. HAYDEN, M.D., Chief of Venereal Clinic at the College of Physicians and Surgeons (Columbia University), New York. Philadelphia and New York: Lea Bros. & Co., 1896.

THIS little manual is an excellent practical exposition of treatment, and is designed especially for students of Venereal Diseases. There is happily in this book none of the exploitation of useless and dangerous fads in the abortion of and treatment of gonorrhea with which we are often bored. Brought up in a conservative school, Dr. Hayden's teachings are judicious and conservative. In a short space much good information is conveyed as to the treatment of all of the manifestations and sequelæ of gonorrhea.

The subject of chancroid is well handled in every particular, and the description of syphilis is concise and graphic. While more works of this character are abortive and unsatisfactory, this one is sound in doctrine and practice and quite full of good therapeutic suggestions.

CLINICAL LECTURES ON MENTAL DISEASES. By THOMAS S. CLOUSTON, M.D., F.R.C.P.E., Lecturer on Mental Diseases in the University of Edinburgh. Fourth Edition, thoroughly revised; fifteen full-page plates. With Folsom's Laws of the United States on the Custody of the Insane. New York and Philadelphia: Lea Brothers & Co., 1897.

PERHAPS no work on mental diseases by any English author has heen so popular as that of Clouston. This popularity is certainly deserved, for the author has put into a colloquial form all the important data relating to the diagnosis, care, and treatment of the various forms of mental disease. The work is avowedly intended as an aid to teaching the fundamental and essential features of insanity. No plan perhaps could have been better devised than the one used by the author for this purpose.

With the greater activity in all pursuits, with the greater keenness of competition in the struggle for life, with the greater segregation of people in the cities, with the increased demands on mental work, in fact with the evolution of civilization, the weaker minds, those unable to stand the strain imposed, are the first to suffer. Insanity is hence on the increase and especially so in the large cities, where all these factors are more extensively at work.

It is the general practitioner whose counsel is first invoked when cases of mental disturbance occur. He should be qualified to detect insanity when it manifests itself, for much of the subsequent result of the case will depend on whether the mental disease has been recognized early. To the general practitioner this work must appeal. For the general features of each form of mental disease are so succinctly given, the clinical picture so adequately and graphically described, that they require no study to impress them on the memory. Clouston certainly deserves the thanks of the profession for this, if for no other reason, that he has removed from the study of mental disease much of the admixture of excessive metaphysical psycology which formerly burdened English psychiatrical science which made the study of psychiatry so distasteful to the general practitioner. He has given to the profession at large a work which is easily understood and which adequately details all the knowledge which a physician need have to qualify him to speak authoritatively on any case which might arise in his professional work.

The method of presenting the various types of insanity adopted by Dr. Clouston is very felicitous. He has utilized the form of lectures, arranging each on a systematic plan. He introduces each by a careful résumé of the subject therein contained. He then goes into the description and clinical features and concludes with a discussion of the prognosis and of the treatment.

The book contains many histories of cases explanatory of the various forms described, making not only very interesting reading, but presenting instructive object lessons.

The work of the publishers is above reproach.

THE TONIC TREATMENT OF SYPHILIS. By E. L. KEYES, A.M., M.D., New York: D. Appleton & Co., 1896.

THIS brochure of seventy-five pages is in no sense a thorough revision of its predecessor of more than twenty years ago, nor can it under any circumstances be considered an up-to-date exposition of the treatment of syphilis, It is simply a repetition of the author's views which have not been accepted by any distinguished syphilographer, nor strange to say, have they been at all changed or modified in all these years although so much of real value has been added to our stock of knowledge on this subject.

MITTEILUNGEN AUS DEN GRENZGEBIETEN DER MEDIZIN UND CHIRURGIE. Erster Band; Drittes Heft. Jena: Gustav Fischer, 1896.

THIS volume bears out the general high standard offered thus far by the editor. Among the articles is one by D. V. Bandler, showing that chloroform produces fatty degeneration of the liver, while ether does not. Von Jacksh states as his opinion that the treatment of malignant tumors by erysipelas serum (Emmerich-Scholl) is dangerous and useless. The remaining articles deal mainly with surgical topics of less interest to the general reader.

THE RETROSPECT OF MEDICINE. Edited by JAMES BRAITHWAITE, M.D., assisted by E. F. TREVELYAN, M.D., B.Sc., M.R.C.P., Vol. 114, July–December, 1896. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited, 1897.

IT is needless to do more than merely call attention to this volume of Braithwaite's Retrospect, the standard work of its kind, which is found in the libraries of medical men the world over. The classification of subjects is the one usually followed in this work, and contains a review of the main contributions to medical literature during the last six months.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, JUNE 5, 1897. NO. 23.

ORIGINAL ARTICLES.

SEMICENTENNIAL OF THE AMERICAN MEDICAL ASSOCIATION, PHILADELPHIA, JUNE 1-4, 1897.

THE PRESIDENT'S ADDRESS.[1]

BY NICHOLAS SENN, M.D.,
OF CHICAGO.

THE American Medical Association was born at the dawn of a great era in the history of medicine. Only a few years before its organization was effected, anesthesia, which has robbed the operating-room of its greatest terrors, came into general use, and at once opened up new fields of usefulness for the surgeon. The new science of bacteriology upon which is based our modern views regarding the etiology and prevention of disease has been founded and firmly established since that time. The principles which govern the present treatment of wounds, conceived by the immortal Lister and developed to the existing state of perfection by a host of his enthusiastic followers, have revolutionized the practice of surgery during the last quarter of a century. Normal and pathologic microscopic anatomy are recent acquisitions to our knowledge of living tissues in health and disease. Aseptic midwifery is the direct descendant of aseptic surgery, and has secured for the lying-in woman the same protection against puerperal complications as the employment of aseptic precautions will largely prevent the occurrence of suppuration, sepsis, and pyemia in the treatment of the injured and patients requiring operative treatment. Anesthesia and asepsis have created visceral surgery.

Our knowledge of chemistry and physiology has been vastly increased during the last fifty years by thousands of earnest and devoted students in possession of improved instruments and apparatus for accurate investigations. During the same time great strides have been made in the practice of medicine and the preparation and methods of administration of drugs. In the light of many of these recent advances we have at least learned that disease is influenced for the better by aiding and assisting rather than by combating and opposing Nature's resources. Transillumination of the body by the wonderful Röntgen ray is the last and most important addition to our diagnostic resources in medicine and surgery. In these events which have startled the medical world in such rapid succession during the last half of the century many members of our Association, dead and living, have taken a prominent and often leading part. In looking about for an appropriate subject for my address at this meeting I have deemed it expedient to utilize my time and this unusual opportunity in discussing as briefly as possible

THE AMERICAN MEDICAL ASSOCIATION, ITS PAST, PRESENT, AND FUTURE.

This is a day of rejoicing to the medical profession of the United States. We celebrate to-day the semicentennial, the Golden Jubilee, of the American Medical Association. It is appropriate that you should have selected Philadelphia as the place of meeting at this time; it was here that the organization of our Association was completed half a century ago. Philadelphia is near and dear to every American citizen, as it is the birthplace of the greatest and most prosperous nation in the world.

It is here that on July 4, 1776, the most precious document in the possession of the American people—the Declaration of Independence—was signed, read and approved by the representatives of a people who craved for freedom, liberty, and independence. It was here that the sweet music of the Liberty Bell was first heard, the reverberations of which reached from the Atlantic to the Pacific, and from the Great Lakes to the Gulf of Mexico, and which has continued and will continue to echo and re-echo over our vast and free country for all time to come. It is a source of congratulation to every and all honest and progressive practitioners of medicine that this document, which was the means of planting a free government upon the virgin American soil and creating a new nation, was signed and heroically defended by America's great physician, Benjamin Rush.

The bloody struggle for independence culminated in the foundation of the great Republic of the United States, which in time gave the medical men an opportunity to establish American medicine upon a free American soil. It is not surprising that the organization of the profession, the establishment of institutions of learning and the foundation of American medical literature met with many difficulties which it required years to overcome.

Most of those who were helpful in laying the corner-stone of this great national institution have gone to their reward; few are left to tell the tale of the early struggles, frequent disappointments, and final triumph. Of those who have been permitted to witness the celebration of the semicentennial, these names are familiar to you all, Nathan S. Davids of Chicago, Alfred Stille of Philadelphia, J. B. Johnson of St. Louis, and D. F. Atwater of Massachusetts.

---

[1] Abstract.

The founders of the American Medical Association were deeply impressed with the dignity and responsibility of our profession; they had for their object a higher standard of medical education, a more general diffusion of medical knowledge, and the creation of a respectable American literature. The idea of organizing a national medical convention originated in the New York State Medical Society and was discussed for the first time at the meeting in 1844. At that time quackery in its worst forms prevailed; the services of the honest physician were undervalued, and his standing in the community compromised on all sides by his less conscientious competitors with and without diploma.

Although the idea of a national convention arose in the New York State Medical Society, the most violent opposition to the organization of the American Medical Association came from New York State.

A meeting was held in Philadelphia, May 5, 1847, in which the organization of the Association was completed. It was attended by two hundred and fifty delegates. The annual meetings were held with regularity and with increasing attendance until the great War of the Rebellion drew a line between the North and the South, which temporarily parted the profession. No armies ever enjoyed to a greater extent the blessings of military surgery than did those of the North and South. The work done by the medical officers on both sides will always occupy an honorable position in the annals of military surgery. The war interrupted the meetings of the American Medical Association, but they again resumed their annual course at Boston in May, 1865. This meeting was attended by two hundred delegates. The only thing which savored of war and which showed the intense excitement which still prevailed, and which caused a serious discord was the expulsion from the Association without trial of Dr. Montrose Pallen, an alleged sympathizer with the South, who then resided in Canada. Dr. Pallen was most unreasonably charged with the heinous crime of introducing smallpox among the people of the North and East. In spite of earnest protests by a number of the cool-headed delegates, he was expelled without trial. It is to the credit of the Association that Dr. Pallen was exonerated and reinstated at the next meeting, which was held at Baltimore in 1866.

After the close of the war, the delegates from the South at once resumed their attendance; the most cordial relations were restored, and many of the largest and best meetings have taken place in the Southern cities.

The influence of the Association has been markedly felt in improving the standard of medical education. Nearly all our medical schools, large and small, now require four-years' attendance of eight months each upon a systematic graded course and, with few exceptions, furnish adequate laboratory and clinical facilities. There is no longer excuse for our medical students to seek foreign universities to obtain a thorough medical education. It requires no stretch of the imagination to predict with certainty that our country will become the center of medical education within twenty-five years, and our medical institutions will be sought by foreign students, as they will in the course of that time furnish facilities for teaching far in advance of those of any other country. Our medical schools are undergoing a rapid evolution by acquiring unlimited financial resources and by the development of model, practical, clinical teachers.

The polyclinics and the post-graduate medical schools, which have recently appeared upon the field of medical instruction and which had their origin in this country, have done good work in furthering the objects and directing the ambitions of the progressive practitioners, old and young. They never have and they never will take the place of medical societies as post-graduate institutions for the enlightenment and advancement of the great mass of practitioners. Medical societies, large and small, are the legitimate and the proper post-graduate medical schools.

Every medical society contains more or less of that morbid material, known as the "political doctor." These men appear more for the purpose of being seen and heard than to promote the legitimate work of the society. They seldom read papers or take part in the discussion of scientific subjects. They know something about parliamentary law, and are anxious that their more timid and less-informed colleagues should know it. This is an unfortunate element in any medical society. Another feature of medical society meetings that demands criticism is the stating offhand of favorable statistics. A sense of honesty should compel participants in any discussion to report their unfortunate as well as their favorable cases, and to record their mistakes as well as their successes. Embellished, painted statistics, too prevalent at this time from ambitious operators, are dangerous traps, and should be scrupulously excluded from the current medical literature. Honesty in medicine, as elsewhere, is always the best policy, and will be amply rewarded at the proper time. Clinical reports are valuable when properly made, harmful and misleading when based on superficial observation and written from memory instead of from an accurately kept case-book.

Prize essays of the American Medical Association have taken a high place in American medical literature, and it must appear plain to everyone that the practice should be resuscitated.

One of the potent agencies in the hands of the members of this Association to place American medical literature upon a sound basis is our official organ, the *Journal of the American Medical Association.* It should be and has already become the mouthpiece of the American medical profession.

One of the present needs of the Association is a permanent home, with an editorial office and a press-room for its official organ, a hall for the meetings at least every three years, a library room for American medical literature, and a memorial home, for paintings, busts of distinguished members of the Association, and a room for a collection of surgical instruments and indigenous medical plants. The present financial status of the Association justifies the taking of the necessary steps to bring such a project into effect at an early date. Such a modern Æsculapian temple would soon become the Mecca of those in search of American medical literature, and a rich storehouse for everything pertaining to the medical history of this country.

Our organization is now complete and in excellent working order. We can devote in the future all of our time to practical scientific work. It is difficult to foretell the possibilities of the second half of the first century of the existence of the Association. It is, however, safe to predict that when the first centennial celebration will be held in this city, fifty years from now, the membership will have increased to seventy-five or one hundred thousand, but the literature of to-day will then be as old and useless as that of fifty years ago. We are now laying the cornerstone and are slowly but surely building the foundation for rational medicine and surgery, and the work of the next fifty years will no doubt contribute still more toward making medicine and surgery exact sciences.

A Mighty Protagonist for Woman's Rights.—In conferring recently upon Fräulein Gabriele von Possanner who received the first doctor's degree ever given by the University of Vienna to a woman, the rector congratulated the candidate in highly complimentary terms, greeting her as a "mighty protagonist for woman's rights," who, "by her great energy and intelligence, has victoriously overcome the manifold obstacles in her way."

SURGERY.[1]

By W. W. KEEN, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THE PRINCIPLES OF SURGERY AND OF CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

As we celebrate on this occasion the semicentennial of the organization of the American Medical Association in this city in 1847, it is very natural and proper that the Address on Surgery should be a review of the work done in the last fifty years, and by contrasting the state of surgery and of surgical teaching in 1847 with that which exists in 1897 to see what progress has been made. The time also is opportune. Last year was celebrated the Centennial of Vaccination and the Semicentennial of the First Public Administration of Ether. Sydney Smith's bitter query in 1820: "In the four quarters of the globe, who reads an American book . . . . what does the world yet owe to American physicians or surgeons?" was answered a quarter of a century later and made all these "four quarters of the globe" our grateful and everlasting debtors. The discovery of an American dentist; first used by an American surgeon; christened by an American physician and *litterateur,* its recent celebration awakened throughout the world the interest, not only of the profession, but also of the entire public; and the strains of our still living poet, novelist, physiologist, and, as we all best love to know him, neurologist, Dr. S. Weir Mitchell—*nihil tetigit quod non ornavit*—as he sung of the "Birth and Death of Pain," have scarce died away before we begin anew our round of celebrations in the anniversary of this now almost venerable "Association."

A most important factor in the improvement, not only in surgery, but in all departments of medicine, has been the immense advance made in medical teaching. If the teachers of fifty years ago were to revisit the scenes of their early labors they would scarcely recognize the medical colleges in which, in their day and generation and with the meager appliances than at their command, they did what we must still recognize as yeoman's work in education. Apparently at that time the entire instruction consisted in lectures, text-books being not even advised. In reply to a letter addressed to the Deans of the Jefferson Medical College, the University of Pennsylvania, Harvard University, and the Medical Department of Columbia University, I am told that no list of text-books whatever appears on the catalogue of fifty years ago.

The course of didactic lectures then began on the second Monday of October and ended soon after the middle of February, and if we take out the holidays and remember that not a few made up for coming late by leaving early, it was quite a possibility for a man to receive his authorization to practice, after practically only two sessions of three months each! The examination was a farce and the diploma a falsehood. Even so late as 1860, when I began the study of medicine, there were no laboratories, except that of anatomy—the dissecting room. I doubt if of the two hundred and odd men who graduated with me in 1862 ten per cent. had ever looked through a microscope or handled a test-tube, palpated a tumor or auscultated a chest. There were no recitations. Nor were there ward classes or other means for actual contact by the student with disease.

---

[1] Abstract of an address delivered at the Semicentennial Meeting of the American Medical Association, Philadelphia, June 3, 1897.

Now we may congratulate ourselves that the majority of the medical schools of the country have a graded course of four years, each covering not less than six and often eight months, not only lectures, but in many instances constant and searching recitations; almost a score of laboratories in which each student actually does the work of observation and experiment; ward classes in which every man is obliged to train his eyes, his ears, his fingers, and his judgment in the examination of patients in every department of medicine; to ferret out the history of the cases brought before him, ascertain symptoms, seek for physical signs, reach a diagnosis, determine the treatment, and often actually to prescribe and to assist at operations.

Of the text-books in use forty years ago, except Pancoast's "Operative Surgery," every one of them was the work of a European. Gross' "System of Surgery," which has probably had a wider influence in educating the profession than any other general surgical text-book issued up to the present time, was first published in 1859. This was far in advance of most of the surgical text-books then in use. The literary labors of American surgeons consisted chiefly in translating foreign surgeries or in annotating American editions of English text-books. Within the last two decades, and especially the last, we all know without my undertaking the invidious task of naming them, how many distinctly American surgeries have been written, and we may say without undue national vanity that they are the equals of any similar European works.

On more than one occasion I have had to call attention to the difference between American surgery and that of Europe. While in the department of the Practice of Surgery, after a full acquaintance and observation with European men and methods, I can state my deliberate conclusion that the best American surgeons are the peers of the best European surgeons; yet in the department of original research and especially of laboratory work, we must confess our very evident shortcomings.

To attempt to impress upon the members of the American Medical Association the need for such original research in this country is a work of supererogation; but I may with propriety insist, with all the ardent and intense conviction I feel, that every one of us, as occasion offers, should urge upon our wealthy liberal-minded fellow-citizens the duty and also the privilege of founding in connection with every medical school, laboratories of research, the good influence and beneficent results of which can never be estimated in paltry dollars and cents. Yet tried even by this commercial standard science pays. The early recognition of the germs of cholera at the port of New York some years ago by preventing the entrance of such a commerce-destroying epidemic, leaving wholly out of consideration the saving of human life, saved to the citizens of the metropolis more millions of dollars than are represented many times over by the cost of all the laboratories now existing in this country. Our merchants should be made to understand, therefore, that even from a financial point of view, to say nothing of the humanitarian, the cheapest means of preventing the enormous business losses which occur from epidemics is by such scientific and hygienic measures as the laboratory makes possible.

Allied to medical teaching, and the most important adjunct to medical literature, is the establishment of extensive medical libraries. In this, as an American, I am proud of my own country. No foreign nation can point with equal pride to any such medical libraries as the last thirty years have developed in this country. Foremost, not only among American libraries, but in the world, is that of the Surgeon-General's Office of the United States Army in Washington. Not only has it gathered thousands of medical books and the 1000 medical journals from all over the world, but the entire library is managed with a liberality which makes it the admiration and the envy of the foreigners. Its treasures are freely at the service of the entire profession of the country, and the publication, under the editorship of Dr. John S. Billings, of its magnificent Index Catalogue has made the whole world debtor to America. We trust that a more liberal Congress may see that if even the small amounts thus far given to it have made it of such immense value, still larger and more generous appropriations would keep it ever in the van.

In addition to this, the libraries of the College of Physicians of Philadelphia, of the New York Academy of Medicine, and of the Boston Medical Library Association are only surpassed by those of the Faculties of Medicine in Paris, of the Royal College of Surgeons of London, and of the Military Medical Institute of St. Petersburg, while those of the Newberry Library in Chicago (thanks to our honored and liberal President), of the New York Hospital, and of the Pennsylvania Hospital rank well with the best European libraries. With such literary opportunities, therefore, had we equally good scientific laboratories, the possibilities of American medicine and surgery would be almost unbounded.

The scientific progress in this half-century of surgery has separated us as by a great gulf from the past. Great theologians, such as a Calvin or a Jonathan Edwards, were they recalled to life, could discourse as learnedly as ever of predestination and free-will; great preachers, as a Beecher or a Spurgeon, could stir our souls and warm our hearts as of old; great jurists, as a Justinian or a Marshall, could expound the same principles of law which hold good for all time; great forensic orators, as a Burke or a Webster, could convince us by the same arguments and arouse us by the same invectives or the same eloquence that made our fathers willing captives to their silver tongues. But to-day a Velpeau, a Sir William Fergusson, or a Pancoast, all of whom have died since 1867, could not teach modern surgical principles, nor perform a modern surgical operation. Even our everyday surgical vocabulary—anesthesia, bacteria, infection, immunity, antisepsis and asepsis, toxin and antitoxin—would be unintelligible jargon to them; and our modern operations on the brain, the chest, the abdomen, and the pelvis would make them wonder whether we had not lost our senses, until, seeing the almost uniform and almost painless recoveries, they would thank God for the magnificent progress of the last half-century which had vouchsafed such magical, nay, such almost divine, power to the modern surgeon.

The development of modern surgery, apart from surgical teaching, libraries, and laboratories, is dependent on several noteworthy factors. These have to do partly with the discovery and development of surgical principles and partly with the development of surgical practice. Now the one and now the other is in advance. Each is the handmaid of the other. In Listerism we see surgical practice outstripping surgical principles, for of Lister it might truly be said that by the "scientific use of the imagination" he saw the germs "when as yet there were none of them." His surgical insight convinced him of the existence of the germs of suppuration years before Ogston's and Rosembaum's discovery of the pyogenic organism. On the other hand the multiplication of these discoveries, which have followed, illustrate the converse—science forging ahead of practice and pointing the way to new achievements in the healing art.

Foremost among the important studies which the past fifty years have seen established on a firm foundation are *Pathology and Pathologic Anatomy*. It is not a little credit to America that the first "Pathology" written in the English language was written by a young American doctor in a then small western town as early as 1839, and it was a graceful tribute to the author when Virchow, the Nestor of modern pathology, held up a copy of the first edition of Gross' "Pathological Anatomy" to the gaze of his fellow-scientists at a dinner tendered to the Nestor of American Surgery.

In spite of Gross' book, however, pathology and pathologic anatomy were almost unknown sciences in 1847. The Pathological Society of Dublin was founded in 1839, that of New York in 1844, that of London in 1846, and that of Philadelphia in 1857. The microscope and especially microscopic methods of staining, section cutting, and the like were in their infancy or may, indeed, be said scarcely to have existed. No accurate views of pathology could be entertained without these aids. What is now the heritage of every first-year student, was beyond the possibilities of the most advanced teacher of fifty years ago.

Allied sciences have been put under tribute to surgery. In physics the discovery of the *Röntgen ray* is so recent as to require only mention.

It is due, however, especially to the development of *Embryology* and *Comparative Anatomy* in combination with pathology, that our views of the nature of the disease have become so much more accurate.

The year before the American Medical Association was organized, the world was startled and surgery revolutionized by the introduction of anesthesia; first of ether in America in 1846 and of chloroform in Edinburgh in the following year. What this has done for the amelioration of the horrors of pre-anesthetic surgery, very few now living can appreciate. Instead of shrieks, cries, and groans of the patient, everything now proceeds with that quiet and leisure which is essential to the performance of many, if not most, of our modern elaborate and prolonged surgical operations. Now, "the fierce extremity of suffering has been steeped in the waters of oblivion and the deepest furrow in the knotted brow of agony has been smoothed away forever." Who could possibly endure the torture of an operation lasting for one, two, or it may be even three hours, when every minute seems an eternity of agony? I would rather be the discoverer of anesthesia than have won an Austerlitz or a Waterloo.

The ideal anesthetic has not yet been obtained.

No one can fail to see that ether or chloroform and also a few others which occasionally replace them have very real dangers. The ideal anesthetic will abolish pain by the abolition of consciousness, *but without danger to life*. That it will be found is as certain as that experiment and progress are our watchwords.

Antiseptic Surgery. — While the exact date of the revelation in surgery due to anesthesia can be fixed, a later revolution in our surgical methods came in so gradually that one cannot name any special day or even year when it was introduced. But, while the day or year cannot be given, the one man to whom this great revolution in modern surgery is due is well known. The name of Lister *primus inter pares* is honored throughout the entire surgical world and his recent distinction as the first medical peer of the United Kingdom is an honor conferred not upon Lord Lister alone, but upon the entire profession and worthily marks a new departure in the recognition of medical science by the Queen.

So far as this country is concerned, the introduction of antiseptic surgery may be said to date from the visit of Mr. Lister to this same city of Brotherly Love at the Centennial International Congress of 1876. Derided as first as a "fad" or as "nothing more than surgical cleanliness," it has now won its way over the whole world. A few laggards in the surgical army there are who even yet do not practice modern antiseptic or aseptic surgery, but the overwhelming majority of the profession recognize that the world owes a debt to Lord Lister, which no honor can pay. His service to humanity will never be forgotten and probably never will be surpassed in its wide-reaching beneficent influence.

As an outgrowth from the practical development of antiseptic surgery has arisen a wholly new science and a wholly new method of practice, which bid fair to revolutionize our modern therapeutics—*Bacteriology and Orrhotherapy*. These are so recent that it is dangerous to prophesy what may occur, but it is not venturing far to predict that fifty years from now we shall be able not only easily to convert infected into non-infected wounds, but that by some means as yet undiscovered we shall be able successfully to combat the infection and prevent the dire ravages of tuberculosis, of syphilis, of cancer, of sarcoma, and possibly even the occurrence of benign tumors. That will be, indeed, the golden age when surgery will be robbed of nearly all its terrors, when a peaceful victory will abolish our present instruments and the majority of our present operations.

Animal Experimentation has had also a very large share in the development of modern surgery. The whole question of the introduction of animal ligatures was begun in America by Physick, who used buckskin, and his follower, Dorsey, who used kid and cut both ends short; Hartshorne, who used parchment, and Bellenger and Eve, the tendon of the deer, and has been solved principally by experiment upon animals in order to determine accurately the behavior of such ligatures in the tissues. Only professional readers can appreciate what a boon to humanity this single achievement has been. Modern cerebral surgery also owes its exactness and success almost wholly to cerebral localization and antisepsis, both of which were first studied by experiment upon animals, and later by the application of the knowledge so gained to man. *Bacteriology would not now exist as a science nor would accurate modern surgery and a large part of modern medicine be possible had experiments upon animals been prohibited, as some zoophilus women who love dogs better than men and women, and even little children, desire.*

Time will not permit me to trace chronologically the introduction of new instruments and new operations.

One of the most striking departments in which progress has been made is in that of the nervous system. In this Mitchell, though not a surgeon, has suggested many surgical advances. I have already quoted South's dictum as to fractures of the skull, a dictum which is now violated, with the happiest results, by almost every surgeon in the land. In addition to this, a very large number of tumors of the brain have been successfully removed, tumors which, before 1884, were considered as wholly outside the domain of surgery. To our English brethren, Godlee, Horsley, and Macewen, above all others, is due the credit of establishing cerebral surgery on a firm basis of right principles and successful technic.

In abscesses of the brain we have a lesion which is still more amenable to treatment, and the number of recoveries now mounts even into the hundreds. Thanks to the otologist, we can now, by proper treatment, in many cases do better than operate on these abscesses, we can prevent them.

Tumors of the spine, since Mr. Horsley's brilliant paper in 1888, have been proved accessible to the modern surgeon. Though Abbé's division of the posterior nerve roots in cases of intractable neuralgia has not been followed by all the success we could wish, it has proved that the operation is a practicable one. While, in the words of the hymn, we have not yet "stretched every nerve," we have almost realized that pious exhortation.

Not only have accumulations within the pleura been evacuated, but Roberts was among the pioneers in the operation of *paracentesis pericardii*, while the surgery of the lung is now only taking its first tentative steps. The pericardium has also been sutured, and even the heart itself has twice been sutured with one complete recovery. We were taught by the younger Gross that the great veins could be successfully tied, and the recent researches of Abbé and Murphy may open a new chapter in the surgery of the arteries by substituting suture for occlusion by the ligature.

The accessory organs in the abdomen have been conquered by the modern surgeon; fifty-seven tumors of the liver have been removed with a mortality as low as 13.5 per cent. The world owes to America the operation of cholecystotomy, since it was first done by Bobbs in 1868, and was popularized by the powerful influence of Sims in 1870. Pancreatic cysts, chiefly through the labors of Senn, are now amenable to treatment. The spleen has been extirpated many times.

The appendix, that meager but most troublesome ancestral vestige which, with the bicycle, has been the faithful friend of the surgeon through the past few years of commercial depression, has been recognized as the real origin of the so-frequent abscesses in the right iliac fossa. Beginning with Willard Parker's paper in 1867 and Fitz's memorable paper in 1886, the treatment of appendicitis and even its much-abused name are distinctly of American origin, and are an immense credit to American surgery.

Until Simon's classical experiments on dogs in 1870 (*Deut. Klinik*, xxii, 137), the kidney was a practically inaccessible organ, but now, when it wanders, we secure it by suture; when there is a stone in it, we open it fearlessly and remove the stone; when it is distended with pus or urine, we drain it; and if it is past hope of recovery, we extirpate it, all with most remarkable success. Even stones in the ureter or a divided ureter, Cabot, Fenger, Kelly, and Van Hook have shown us, can be dealt with successfully.

The surgery of the pelvic organs has, one may say, been created since 1847, but its triumphs are so many that time allows me only a word. Sims' treatment of vesicovaginal fistula and his introduction of silver wire in 1852 was distinctly an American triumph.

A hasty review such as has been given of the improvements in surgery within the last fifty years does much more than show us the adroitness, audacity, and success of the modern surgeon. That is the thing which strikes us most as surgeons, but we must regard all these improvements also from the side of the patient and the family, and see what it means. It means a prolongation of life by operations which, while not without pain and suffering during recovery, have been robbed of all their primary terrors by anesthesia, and most of their subsequent pain and suffering by antisepsis. It means that patients who, in 1847, were hopelessly consigned to the grave, after weeks and months of suffering, are now, in the vast majority of cases, rescued from death. It means that families formerly bereft of husband or wife, parent or child, and left to spend years of sorrow, of suffering, and, in many cases, of poverty, because the breadwinners were taken away, have now restored to them their loved ones, in health and strength and usefulness. It means that the hecatombs of a Cæsar, of an Alexander, a Napoleon, are offset by the beneficent labors of a Morton, a Warren, a Lister, who are, and who for all time will be, blessed by many a poor patient who never heard of them, instead of being cursed as the destroyers of nations and of homes innumerable. It means that man's inhumanity to man shall be replaced by a scientific and Christian altruism which sheds blessings and benefits on the whole human race, seeing in the patient, whether saint or sinner, only a human being who is suffering from accident or disease, whom it is the province of the surgeon, in imitation of Him who went about doing good, to restore to health and happiness. Even where life cannot be prolonged, the agonies of death itself can be soothed by his hand and his fruitful skill.

What the future has in store for us we can only dream. Two diametrically opposing tendencies are prominent in modern surgery: radical interference with disease, so that there is scarcely now a single organ or portion of the body not within our reach; yet, on the other hand, a remarkably conservative tendency in cultivating remedial rather than radical surgery. Joints so diseased as once to require amputation are now treated conservatively with the best results. Ovaries, a portion of which can be preserved, are kept in the abdomen; kidneys once doomed to extirpation are now partially removed, and bones so diseased that they then required amputation are now excised and the limb preserved. Experiments upon animals have recently given us wholly new views of infection and of the origin of many diseases, and also the little knowledge that we yet have as to either natural or acquired immunity, and to a consequent orrhotherapy.

It is, I believe, on these lines that our more immediate future triumphs will be achieved. We have discovered the actual cause of tetanus, tuberculosis, erysipelas, suppuration, and a host of other diseases and conditions, of the cause of which we were wholly ignorant a few years ago. The cause of many other disorders, both medical and surgical, still remain hidden from our view. We know almost nothing of the origin of benign tumors, and are groping to discover the origin of cancer, sarcoma, and other malignant growths. When we have discovered the cause, we are nearly half way, or at least a long way on the road to the discovery of the cure, and I think it not unlikely that in 1947 your then orator will be able to point to the time when a definite knowledge of the causes of these diseases was attained and probably to a time when their cure was first instituted.

That will be a surgical paradise when we can lay aside the knife and by means of suitable toxins or antitoxins, drugs, or other methods of treatment, control inflammation, arrest suppuration, stay the ravages of tuberculosis, or of syphilis, abort or disperse tumors, cure cancer, and it may be, so prolong human life that all of his then audience will die either of accident or of old age. Would that you and I could be alive in 1947 to join in the glorious surgical Te Deum!

STERCORIN AND CHOLESTEREMIA.[1]

By AUSTIN FLINT, M.D.,
OF NEW YORK;
PROFESSOR OF PHYSIOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; CONSULTING PHYSICIAN TO BELLEVUE HOSPITAL; CONSULTING PHYSICIAN TO THE MANHATTAN STATE HOSPITAL, ETC.

LOOKING far into the future, it seems possible that our successors may fix upon the month of May, 1946, as the true centennial of the American Medical Association, dating the origin of this body from May, 1846, when a convention of representatives of our profession, held in New York, proposed the formation of a national association, which was formally organized in 1847.

It is not too much to say that the convention of May, 1846, marked an era in the history of medical organization in the United States. It had become necessary that the medical profession should be unified and separated from those practising under sectarian designations, particularly as at least one sect was beginning to secure the confidence of men otherwise intelligent, and assumed to practice medicine on a scientific basis. The status of medicine forty years ago is quite within my recollection. Medicine is not, never was, and never will be an exact science; but it always has been progressive, and never more so than at the present time. Fifty years ago, perhaps, medicine merited the reproach of being the least exact of all sciences; but its progress within the last fifteen years has been so prodigious that it is now in advance of them all. Fifty years ago, skill in the diagnosis of certain diseases was acquired only by long practice and large experience. With our present methods, properly employed, it is impossible to make an error in the diagnosis of many of the diseases which formerly presented difficulties, such as typhoid fever, tuberculosis, diphtheria, cholera, and most of the neoplasms. To say that pathology has been revolutionized within the last ten or fifteen years is not enough—a new pathology has been created, and with it have come an intelligent hygiene, prevention, and therapeutics, based upon exact scientific knowledge. As no human imagination fifty years ago could have pictured the condition of the medicine of to-day, so it to-day seems impossible to imagine the progress of another half-century. Never, since medicine became a science, has medical history been made so fast as now. Between the time of writing and of delivering this address, scientific labor may give birth to a discovery destined to revolutionize some department of medicine, as Pasteur, Koch, and their followers have revolutionized therapeutics, and as Lister created a new surgery.

It is a matter of congratulation that the name of this body was early changed from "National" to "American" Medical Association. We have good reason to be proud of American medicine, and our great representative association may properly claim a distinctive title. When one is able to call up at random the discoveries in gastric digestion, anesthesia in surgery and obstetrics, the successful ligation of the arteria innominata, the operation for vesicovaginal fistula, ovariotomy, and intestinal anastomosis, to say nothing of minor advances in medicine and surgery, can we not claim a distinctive place for American medicine?

It is the prerogative of the presiding officer of this Association to make recommendations, and this is not the province of one appointed simply to give an anniversary discourse. The remainder of the time that has been placed at my disposal I shall venture to occupy with a subject which I hope may not prove entirely unworthy of your attention.

Stercorin and Cholesteremia.—While the presentation, on this occasion, of researches made and published thirty-five years ago—viewing the question from a physiologic standpoint—calls for an explanation and perhaps an apology, none is required if their great importance in relation to the pathology of the liver be considered, especially as cholesteremia is by no means accepted as a distinct pathologic condition. Were it not that stercorin has just been rediscovered in Germany by two eminent physiologic chemists, who make no mention of its full description in 1862 and have even called it by another name, I probably should not have repeated and extended my original observations. As it is, however, I feel that I may properly, as an American investigator, make my reclamation before the American Medical Association.

---

[1] Abstract of an address delivered at the Semicentennial Anniversary of the American Medical Association, Philadelphia, June 2, 1896.

Although my paper, published in *The American Journal of the Medical Sciences* in October, 1862, received an "honorable mention" and substantial recognition from the Institute of France, and my observations have been verified and extended by French and German investigators, many writers on physiology and pathology, even the most recent, fail to recognize such a substance as stercorin and, in treating of cholesterin, speak of its function as obscure or unknown.[1] In "An American Text-book of Physiology," Philadelphia, 1896, cholesterin is described as a constant constituent of the bile, very widely distributed in the body, and eliminated by the liver cells from the blood. "That it is an excretion is indicated by the fact that it is eliminated unchanged in the feces." Stercorin is not mentioned. As a matter of fact, cholesterin does not occur in the human feces in health, and its presence in this situation is exceptional.

In Hoppe-Seyler's *Zeitschrift für Physiologische Chemie*, Strassburg, 1896, is a paper by Bondzynski and Humnicki, entitled "The Destination of Cholesterin in the Animal Organism." The authors claim to have discovered a new constituent of the human feces, which they call "koprosterin." This substance is identical with stercorin, fully described in 1862. The original stercorin, of which specimens obtained in 1862 are in my possession, was extracted from the human feces by the following process: The dried and pulverized feces were extracted with ether. The ethereal extract was passed through animal charcoal and afterward evaporated. The residue was then extracted with boiling alcohol. The alcoholic extract was treated with potassium hydrate solution, at a temperature near the boiling point of water, in order to remove the fats by saponification, which were washed out with water until the filtrate was neutral and perfectly clear. The filtrate was dried, extracted with ether, and the ethereal extract evaporated to dryness and extracted with boiling alcohol. The stercorin was obtained from the alcoholic extract by repeated crystallization. This process was exactly repeated in our recent observations, and, at the same time, stercorin was extracted by the process described by Bondzynski and Humnicki.

The opinion expressed by Hoppe-Seyler, Hofmann, and indeed many others, that stercorin simply is impure cholesterin, cannot have been based upon a practical knowledge of this substance. Stercorin has a well-defined formula—$C_{27}H_{48}O$—which has been calculated and verified by the formation of esters. Its crystals are quite different from crystals of cholesterin, and are invariable in form, arrangement, and color. It was extracted by methods practically the same as those used in the extraction of cholesterin. In view of these facts, to assume that stercorin is an impure substance, one must deny a positive scientific basis to organic chemistry.

In the recent, as well as in the original, observations, it was clearly shown that cholesterin is changed into stercorin in passing down the intestinal canal. I found that this change involved processes incidental to intestinal digestion. Cholesterin and no stercorin was found in the feces of fasting animals and in the meconium. Bondzynski and Humnicki found and increased proportion of "koprosterin" in human feces after the ingestion of a certain quantity of cholesterin. They also showed that cholesterin unites readily with bromin, while "koprosterin" forms no such combination; and, indeed, by the use of bromin, these two substances may be separated when they exist together. They confirmed the empirical formula for their product by the formation of a number of esters.

It is now generally admitted that the bile, in addition to its function connected with digestion, contains one or more excrementitious matters. Taking into consideration the various ingredients of the bile, there seems to be but one which can logically be compared to urea. Cholesterin is found in many of the tissues and organs ot the body and exists in the blood. Likening it to urea, it becomes a question whether it is formed in the liver and discharged in the bile or is merely separated from the blood by the liver and excreted.

Passing from these observations to the pathologic relations of cholesterin, after examining three specimens of normal blood and finding the proportion of cholesterin from 0.445 to 0.751 of a part per thousand, examinations were made of the blood of patients with simple jaundice and those with what is called icterus gravis, the cases terminating fatally with grave nervous symptoms. In a case of simple jaundice, terminating in recovery at the end of about four weeks, the blood contained 0.508 of a part per thousand; well within the limits in normal blood. In a case of jaundice with cirrhosis, terminating fatally with serious nervous disturbance, the blood taken six days before death contained 1.850 part per thousand of cholesterin—an immense increase over the normal proportion. In this case, on *post-mortem* examination, the liver was found contracted, and the gall-bladder was shrunken, containing only about seven cubic centimeters of bile.

The question of cholesteremia has been much discussed since 1862, for the most part with scant approval or without acceptance. However, Picot,[1] in 1872, reported a fatal case of "grave jaundice" in which he determined a great increase in the proportion of cholesterin in the blood, 1.804 parts per thousand. Many attempts have been made, also, to produce toxic effects by injecting cholesterin into the blood, but most of them have been unsuccessful on account of mechanic obstruction of the blood-vessels. In 1873, however, Koloman Müller[1] succeeded by injecting cholesterin rubbed with glycerin and mixed with soap and water. In five experiments on dogs, injecting in each 0.045 gram of cholesterin, he produced a complete representation of the phenomena of "grave jaundice."

[1] Foster, "A Text-book of Physiology," 1895, p. 356.

[1] *Journal de l'Anatomie*, Paris, 1872, tome viii, p. 247, *et seq.*

It must be remembered that the liver is by far the largest gland in the body; that it secretes a fluid which is known to have a double function, one connected with digestion and the other with the elimination of cholesterin; that the blood from the digestive tract all passes through this organ, where it undergoes certain changes; that it probably stores up the products of amylolytic digestion in the form of glycogen; that it arrests certain poisons, and that it is the chief organ concerned in the production of urea, which is discharged by the kidneys. It may have other uses in what is now called internal secretion, in addition to that of destruction of blood-corpuscles and the change of hemoglobin into bilirubin. With all these known varied uses of the liver, however, the pathology of hepatic diseases is most obscure. We do not know, even, the cause and mechanism of the formation of gall-stones, which are often composed almost entirely of cholesterin.

The term, acholia, as used in pathology, now means very little and conveys no distinct idea of the causes of the nervous symptoms which attend this condition. The term cholemia is generally regarded as almost synonymous with jaundice. If cholesteremia be recognized as a distinct pathologic condition, with symptoms due either to the accumulation of cholesterin in the blood, acting as a toxic substance, or to imperfect separation of cholesterin from the nervous tissue, a positive advance will be made in our knowledge of the pathology of many obscure liver disorders.

The quantitative estimation of cholerestin in the blood is not difficult, and it does not require more than from four to six or eight grams of blood. The only tedious manipulations are the drying, saponification, and weighing; and these are readily done in a well-appointed laboratory. Some process may be devised which will expedite this extraction. If examinations of the blood were to be made in cases of obscure nervous disturbance, in epilepsy, and other disorders of this nature, it is possible that cholesterin may be found to play an important part in their pathology. The fact that bromin readily combines with cholesterin, taken in connection with the wide use of the bromids in diseases of the nervous system, is very suggestive. May not the bromids promote the elimination of cholesterin, a substance which is so insoluble and which forms few combinations? These points seem well worthy of the consideration of pathologists and therapeutists. Certainly the physiologic and pathologic relations of cholesterin offer a wide, and perhaps fruitful, field for further observation.

MECHANISM AND TREATMENT OF PERINEAL LACERATIONS.[1]

By JOSEPH PRICE, M.D.,
OF PHILADELPHIA.

MANY men who profess intelligence of surgical procedures instituted for the relief of abdominal difficulties are entirely unprepared to deal with injuries of the perineum or cervix. There are even many of large obstetrical practice who appear sincere in declaring that no rupture of the perineum has ever occurred in their work, and that all their patients have normal perinea. There is but one explanation of this. We need only recollect that prominent instructors in obstetrics have declared that a laceration of the perineum is practically impossible under their various methods of procedure, and therefore omit even a preparation for the contingency. We cannot so easily comprehend, however, the negligence of practitioners whose personal motives should have induced a greater care in this matter than we now observe.

It is discouraging to me to consider the haste with which our younger physicians attempt the larger work of abdominal surgery and seem not to appreciate the necessity of a minute understanding of the functions of tissues, especially those involved in and surrounding organs with which we have to deal in obstetric practice. It is a matter which no amount of talk will remedy. As mere economy in this ambition I would suggest that a little more attention be directed to this particular subject of perineal lacerations. That a rupture of the perineum may be so entirely concealed as to eventually deceive the most careful examiner there is no doubt; neither do I doubt that the search is often omitted or unintelligently performed.

The teaching that these repairs are easily made has led to much unskilful treatment, treatment that leaves the patient in a worse condition than existed before anything was done in the way of attempted repair.

[1] "Ueber Cholesterämie," *Archiv. für experimentelle Pathologie und Pharmakologie*, Leipzig, 1873, Bd. i, S. 213, *et seq.*

[1] Read at the Semicentennial Meeting of the American Medical Association, Philadelphia, June 1–4, 1897.

The supposed condition tempts to the undertaking of that which, while not the most difficult surgery, requires, from the very delicacy and sensitiveness of the parts, careful and refined work.

It would not be unprofitable for a surgeon to undergo an apprenticeship in a mechanic's workshop where his instructor could explain the cycloidal and epicycloidal lines upon which his gear wheels must be formed, or allow him to experience directly the very disastrous results of the slightest neglect in manipulating those very exact little dealers, machines. Then I think he would appreciate the responsibility of altering indefinitely the organs of a human being, or of suffering them to remain unrepaired where accident has changed or broken normal relations. True, he has in Nature a wonderful corrector of his mischief, whose effort is ever for cure. Nature has been defined "as the good will of God expressed in facts;" nowhere has this good will been more marvelously expressed than in the correction of our errors. But it should be kept in mind that Nature despises an irrational, blundering performance as she does a vacuum.

Our surgical triumphs are largely those of common sense; they are the result of reducing everything to the simplest form consistent with completeness. There is not sufficient appreciation of the value of simplicity and directness, nor of completeness. In plastic surgery, as in all other, I would aim toward such an end. I would do an operation that would restore the perineum to as natural a condition as possible. A great deal depends on whether the tear be partial or complete, central or lateral.

It must be remembered that the perineum proper is made up of all muscles composing the lower *pelvic diaphragm*, and that this pelvic diaphragm is anatomically the adjunct and coefficient of the upper or true diaphragm of the respiratory apparatus. This fact is of value in estimating the importance and significance of pelvic lacerations. It should be remembered that every perineal tear begins on the inside, or, in other words, proceeds from above downward, from within outward—it happens only as an accident of extreme rarity that there is any important outside tear without a co-existing internal tear. And beside this fact another one is to be placed—there may be most serious internal laceration without any external manifestation, so far as the skin is concerned. There may be so much over-distension of the tissues that all pelvic support is absent without any evidence of real laceration. This sort of a tear bears the same relation to evident laceration as does a free open incision of a muscle to a subcutaneous division of a muscle. Complete perineal laceration is a term usually applied to tears through the sphincter. These tears are regarded as the most important on account of the discomfort they entail. Women with the sphincter ani lacerated have a miserable existence, though apart from this the other complications and real calamities of pelvic lacerations are often absent. The sphincter may be torn through, and still there may be no sagging of the pelvic contents, no cystocele, and no rectocele, no prolapsus uteri. This fact is explicable: in a distinctly central tear the lateral attachment of the muscles and fascia are uninjured, while the middle junction of the perineal muscles is simply split, divided, or separated, and consequently the support, while diminished, is sufficient to withstand the pressure of the pelvic contents. The resistance of the muscles is diminished—not destroyed. Complete tears, in my opinion, ought to be considered as including all deep fascial and muscle lacerations, either on one or both sides, with a co-existing or non-co-existing sphincter tear, as the case may be.

All these tears should be approached as distinct surgical lesions, to be repaired in the line of their anatomic destruction, and not as cosmetic operations, the object of which is to obtain superficial appearances without regard to completeness and utility. Heaping up of tissue, outside the lines of resistance, and tension or mere thickening of the mucous membrane and skin does not make a true perineum; neither does a set of outside sutures, however much they may draw the parts together, afford any anatomic counterpart of a perineum. From this point of view all the so-called flap-splitting operations for perineal tears are only puckering operations, bringing parts within the sutures that have never been severed, and in many cases taking them out of their proper relations. Flap-splitting operations are really *misleading superficial procedures.* They attack tissues not in the lines of their real rupture, and do not and cannot go to the real origin of the tears. They do not afford an end-to-end adaptation of the torn muscle, but substitute for this a lateral apposition, simulating *end-to-end* restoration, which can be readily demonstrated. The Emmet operation, as originally devised and afterward modified by him, is the foundation for all successful operations on the lacerated perineum, either with or without *sphincter* tear. This, it is to be remembered, is always an inside operation.

Even in sphincter tears, two or three outside stitches are all that in a majority of cases are necessary. Its so-called modifications are extensions only of the original idea of Emmet, and are only original in the use of a greater denudation, with a consequent increase in the number of stitches.

The loss of tissue objected to in the Emmet operation is more than equaled or compensated for by the lateral apposition. Moreover, it is to be kept in mind that the sphincter is a distinct anatomic unit —and that any flap-splitting which attempts to repair this, together with other laceration, is over-reaching itself and attempting too much in its efforts at one time to repair distinct lesions. When the fascia is injured, in addition to the sphincter tear, the injury is to be remedied by the ordinary Emmet operation. This operation, by its denudation, brings into relation large triangular levels on one or both sides, putting into relation the torn ends of the torn muscles. When the sphincter ani is ruptured its torn ends are drawn outward and backward until they lie on a line with the posterior line of the rectum. In other words, the muscle is straightened. The depressions on either side of the anus are caused by the torn ends of the muscle retracting the mucous membrane, thus forming the characteristic dimples.

The denudation should be made so as to expose the cut ends of the muscle on either side, and continued upward into the bowel as far as the laceration extends, between the rectum and vagina, into the rectovaginal tissue. Two sets of sutures are to be used ordinarily. The first is the deep-set vaginal, and restores the rectovaginal septum, bringing the parts into the relation they would assume were there no sphincter tear, while the other sutures are introduced as in an ordinary or fascial tear. The rectal or vaginal sutures are, of course, the first to be introduced. If catgut is used for the closure of the bowel, their method of introduction is left to the choice of the operator. If silk, silver wire, or silkworm-gut is used, the sutures must be introduced so as to be tied, twisted, or shotted on the vaginal side. After the tear into the rectovaginal septum has been closed, attention must be given to bringing the ends of the sphincter accurately into apposition. For this purpose the needle must be introduced at the edge of the torn muscle, directed upward, then backward, to the internal edge of the muscle, so as to bring the retracted central portions to a level. If this procedure is adopted on both sides, a flat surface of muscular tissue is obtained and the apposition will be complete. Failure of this operation is easily discoverable. If a fistula persists, there is generally a more or less complete failure of the operation, and the desired effect is not obtained.

To insure the complete success of the operation, extreme care is necessary to restore the bowel and to treat the sphincter as an integral portion of the bowel, bringing the sutures down so as to leave no pocket between the bowel proper and that portion into which the sphincter is inserted.

The instruments formerly suggested as the essentials for perineal repair, of which the Peaslee or Baker-Brown needle may be taken as the type, have no place in the delicate scientific surgery of these parts. Big sutures, heavy ligatures, clumsy instruments have no more place here than in other surgery. The ordinary short, strong sewing-needle serves the purpose fully in most cases, though the Emmet strong, fine, short needle for general use is preferable. Silkworm-gut or silver wire are the preferable sutures. These, with a needle-holder without lock, shot-compressor and tenaculum, are really the only instruments required. Here, as in all surgery, few and simple instruments serve best.

CONDENSED MILK; ITS USES AND LIMITATIONS IN INFANT-FEEDING.[1]

BY CHARLES GILMORE KERLEY, M.D.,
OF NEW YORK;
LECTURER ON DISEASES OF CHILDREN IN THE NEW YORK POLYCLINIC; ASSISTANT ATTENDING PHYSICIAN TO THE BABIES' HOSPITAL.

THROUGH the ignorant use of condensed milk as an infant food, many lives are lost yearly in our larger cities, while, on the other hand, to its intelligent use may be attributed the fact that many lives are saved. In considering the value of any artificial food for infants, we must be governed by one standard—that of mother's milk, the nourishment the child has a right to expect.

An analysis of mother's milk shows that it contains from 3½ to 4 per cent. of fats, 2 per cent. of proteids, and 7 per cent. of sugar. The analysis of a condensed-milk mixture, when diluted for use in the proportion of one part in six of water, gives us 1 per cent. of fat, 1.2 per cent. of proteids, and 8 per cent. of sugar, a greater part of the latter being cane sugar. It is extremely rare, however, that we meet with a child that is being fed on so strong a mixture, for the reason that it will almost surely produce colic and indigestion. The condensed-milk-fed children who come under my care are being fed, as a rule, on a mixture diluted to one in twelve or one in fourteen. The one-in-twelve dilution gives a mixture containing 0.5 per cent. of fat, 0.6 per cent. of proteids, and 4 per cent. of sugar. Comparing this with breast-milk, it may readily be seen how inefficient it must be for a permanent diet. Even if the one-in-six dilution is given, it will still be inadequate.

Apparent as the shortcomings are, many children will do comparatively well in very early life on the weaker dilutions, that is, one-in-twelve or one-in-fourteen. There is sufficient of the carbohydrate to produce heat, and the proteids, though small in quantity, furnish the requisite amount of nitrogen. The proteid of cows' milk differs from that of woman's milk in chemical composition, and is more difficult of digestion. This we have known for a long time; but there is another important difference: The child requires a smaller amount of the proteids of cows' milk, although the relative nutritional properties of the proteids cannot be exactly determined. This is not a supposition, but a fact that has been demonstrated clinically to my satisfaction, and it helps to explain why infants will do well for a time on condensed milk. Many thrive on the ordinary canned variety, diluted one in twelve, until the third month is reached; then the demands of the system exceed the supply of fat and proteids. If the diet is continued, rachitis and malnutrition of varying degrees will almost always ensue.

---

[1] Read at the Semicentennial Meeting of the American Medical Association, Philadelphia, June 1-4, 1897.

Of the many hundred marasmic and rachitic infants that I have had an opportunity to observe, fully ninety-five per cent. had been fed on the meal foods or on canned condensed milk, chiefly the latter. This ill-conditioned class of children, with their starved muscular and nervous systems and catarrhal tendencies, fall an easy prey to the infectious diseases during the entire year, to bronchopneumonia in winter, and to the gastro-intestinal diseases in summer. Notwithstanding what has been said, I occasionally meet with children that have been fed exclusively on condensed milk up to the ninth or tenth month, and that have thrived fairly well. These will usually present some evidences of bone rachitis, although the development otherwise will apparently be normal. These infants are held up to us as evidences of the value of the diet in question, and we hear of a great many more than we see. These isolated instances are to be explained by the fact that there are a few infants whose adaptation to abnormal conditions is so great that they cannot be injured by ordinary improper feeding.

An illustration of this was furnished by the case of a well-nourished one-year-old infant that was brought to the out-patient department of the Babies' Hospital to be treated for bronchitis. Its diet up to the third month had been mother's milk and condensed milk. Since then it had consisted of meat, potatoes, bread, rice, crackers, soup, and condensed milk. Tea and coffee were given when the child wanted a drink, and it had beer on Sundays and holidays. Another case in point: A babe six months of age was brought to the dispensary on account of a sharp attack of diarrhea and vomiting. In addition to medicinal treatment, a diet of barley-water and egg-water was ordered. Recovery followed shortly, and the mother was instructed to gradually resume the former milk diet. I did not see the patient for two months, when he was brought to the dispensary because of an attack of whooping cough. While being undressed, preparatory to an examination of the chest being made, I noticed that the stomach was enormously enlarged. Upon inquiry as to the cause, the mother replied that she supposed it was due to the large quantity of egg- and barley-water taken. A second gastro-intestinal attack had followed the resumption of a milk diet, and the mother thought it would be easier to keep him well on egg- and barley-water than to keep him ill on milk. He had ingested from five to six pints of this preparation daily, and although rather pale, was strong and active. These children thrived for the same reason that older children sometimes thrive on an exclusive diet of canned condensed milk or of plain meal, but the badly fed children who manage to escape resulting disease because of special powers of adaptation are few in comparison with the number that fail. In short, condensed milk is unsuitable as a permanent infant food, in that it is inadequate to the demands of the growing child.

In spite of what has been said, my out-patients consume hundreds of pounds of condensed milk yearly, and under my direction. If condensed milk is so unsatisfactory a diet, as generally used, when, how, and under what conditions may its use be advanced? To begin with, I employ condensed milk voluntarily under one condition only. I meet with a few delicate infants, usually from two to ten weeks old, who must be bottle-fed, and for whom it is impossible to modify fresh cows' milk. These children are unable to assimilate the proteids contained in fresh cows' milk in sufficient amount to thrive; and under these circumstances I order the unsweetened or canned condensed milk, preferably the former. A dilution of one-in-twelve will oftentimes be borne without inconvenience, and the child will do well for six or eight weeks, when it will be able to digest a modified fresh cow's milk containing a low percentage of proteids. Why the children are able to digest and assimilate the proteids of condensed milk when those of fresh milk will produce illness, I am unable to explain.

I employ the canned condensed milk because I am obliged to do so in the case of several hundred infants each year. I use it among the very poor, the ignorant, and the careless who bring their children to the dispensary, and for this reason: The very poor cannot afford cows' milk at 6 or 8 cents a quart, neither can they buy refrigerators or ice to properly keep the milk. The ignorant cannot appreciate or follow out the instruction as to the dilution and care of the milk. This class also may be included under the first heading. We occasionally meet with representatives of the careless class in the better walks of life. They insist upon feeding condensed milk to their children against our wishes, their excuse being that such a plan is the easiest to follow. The wives of the American and Irish laborers comprise a goodly number of the indifferent class. The proprietary foods are happily excluded from the uses of the poor, for the reason that they are expensive.

Our only resource the year round with many infants is the sweetened canned condensed milk. It is inexpensive, it will keep sweet several days in hot weather without ice, on account of the added amount of cane sugar, and it is easy of administration. Having this preparation with its imperfections forced upon us, how are we to use it? We have seen from the chemical analysis that the percentage of proteids and fats is low. We would not expect children to be properly nourished on it, and clinically we know that they are not. In the feeding of infants the percentages constituting a proper diet should ever be borne in mind, and as nearly as possible correct formulæ should be worked out on this basis. We must supply to the condensed-milk-fed infant the deficient amounts of fat and proteids. If the parents of the patient are well-to-do, cream may be added in proper proportion to make up the requisite amount of fat. Among dispensary patients, cod-liver oil supplies the deficiency. The dose must vary according to the age, the ability of the child to digest it, and the season of the year. I prescribe from 10 drops to a dessertspoonful, three or four times daily after feeding. As a rule it is taken readily. During the very hot weather the dose must be reduced or the oil discontinued if there are evidences of gastro-intestinal disturbance.

The proportion of proteids will still be low, but they may be increased by adding the condensed milk to a meat broth. One pound of lean beef is boiled in one quart of water until the liquid is reduced to one pint. It matters little what portion of the animal is selected so long as lean muscle-fiber is used. The broth prepared in this way, according to the analysis of John S. Adriance of New York City, contains 0.8 of 1 per cent. of proteids; so that if one part of condensed milk is added to twelve of broth, the mixture will contain 0.5 per cent. of fat, 1.4 per cent. of proteids, and 4 per cent. of sugar. This will answer for a child of three months of age. Fat is supplied by the use of cod-liver oil. When the sixth month is reached, one part of condensed milk may be added to nine of broth. The percentages then will be, approximately, .75 per cent. of fat, 1.7 per cent. of proteids, and 5 per cent. of sugar. This, with cod-liver oil, will answer until the eighth or ninth month, when the critical nursing period will have been passed and barley and oatmeal gruel, with other meal mixtures, may be allowed.

The conclusions arrived at are as follows:

1. In the artificial feeding of infants, always determine as exactly as possible the percentages of the food constituents.

2. Condensed milk alone is an indifferent substitute for mother's milk, no matter what the age of the infant may be.

3. Condensed milk alone should not be given after the third month.

4. Condensed milk, fortified, may be made an acceptable diet for infants; alone, it is a food upon which a certain number of children exist until age or changed conditions allows of a better diet; and inasmuch as there is nothing to take its place among the very poor, its value to them is inestimable.

CLINICAL MEMORANDA.

THREE CASES OF OBSCURE LARYNGEAL DISEASE—TUBERCULOSIS, SYPHILIS, EPITHELIOMA.

BY CHAS. H. KNIGHT, M.D.,
OF NEW YORK.

CASE I. *A Case of Tuberculosis of the Larynx Simulating Malignant Disease.*—A man, about sixty years of age, came to my clinic at the Post-Graduate Hospital in October, 1896, presenting many of the features supposed to be pathognomonic of laryngeal cancer. The left half of the larynx was involved. It was infiltrated and immobile, and a smooth, reddish, sessile tumor projected into the cavity of the larynx from the left ventricular band. There were two or three small, hard, and sensitive glandular swellings at the level of the larynx near the anterior border of the left sternomastoid muscle. The left ala of the thyroid was sensitive to pressure, and the patient complained of spontaneous pain shooting up to the left ear. There was no tuberculous history. I made a provisional diagnosis of malignant disease. Within a few days suspicious pulmonary signs were reported, a little later tubercle bacilli were found in the sputum, and in the course of a week or ten days the right side of the larynx was invaded. Both arytenoids became infiltrated and clubbed, and an ulceration could be seen upon the laryngeal surface of the epiglottis, which itself had become symmetrically thickened and turbanned. The laryngeal picture was then almost typical of tuberculosis. This patient has since died of general tuberculosis. Such an anomalous development of tuberculosis in the larynx as this is extremely misleading, and in a younger subject might encourage unwise surgical intervention, especially if the progress of the disease is less rapid and the exhibition of unmistakable symptoms more tardy.

CASE II. *A Case of Tuberculosis of the Larynx Complicated by Latent Syphilis.*—In September, 1895, a gentleman was sent to me with a diagnosis of pulmonary tuberculosis. He had been losing flesh, having night sweats, and was annoyed by a hacking cough, with considerable expectoration. His voice had been very husky for several weeks. Four years ago this patient had an attack of gonorrhea and an ulcer of the frenum, which healed promptly under calomel powder. No secondary symptoms were ever discovered, and no antisyphilitic internal medication was given. The larynx was rather hyperemic. The arytenoids were distinctly clubbed. A somewhat superficial ulcer involved the left margin of the epiglottis and the adjacent aryepiglottic fold. No tubercle bacilli could be found in the sputum. A month later this patient returned to me with all his symptoms aggravated and with decided extension of the local lesions. Tubercle bacilli were found in numerous specimens of sputum examined. He was advised to go at once to Southern California. Improvement began immediately after his arrival there, but presently he became worse again. In the course of four months an ulceration appeared on the posterior wall of the oropharynx, so suspicious in character that his attending physician put him on mixed treatment. At the same time the ulcerated surfaces in the pharynx and larynx were sprayed with a ten- to fifteen-per-cent. solution of lactic acid. The dose of iodid of potash was gradually increased to 40 grains three times a day, and under this treatment all the symptoms underwent marked amelioration. The ulcers healed, the swelling of the arytenoids subsided, and the voice was gradually restored. At the same time a rapid and surprising improvement in the general condition took place.

At the expiration of a year this patient presented himself to me for examination in apparently perfect health. No traces of his old trouble could be detected, except certain cicatrical bands crossing his posterior pharyngeal wall which were positively characteristic of old syphilis. He has resumed the practice of his profession in the East, and up to the present time has had no recurrence of the symptoms. Several questions difficult to answer are suggested by the foregoing case. They relate to the time and mode of syphilitic infection and to the influence of that accident upon the tuberculous disease. The evidence of the existence of each of these dyscrasiæ seems to be indisputable. There is but little doubt in my own mind that the sore referred to as having occurred in 1894, although very insignificant and of short duration, was a genuine infecting chancre. As often happens in such cases, early secondary symptoms, if they develop, escaped detection because of the very unimportance of the primary lesion. The arrest of the tuberculous process may be fairly attributed to change of climate, but it seems not unreasonable to assume the possibility of an antagonism between the tuberculous and the syphilitic diatheses which might have a mutually modifying influence.

CASE III. *A Case of Epithelioma of the Larynx Disguised by Marked Remission of Symptoms.*—The patient was a lady about forty years of age who came under my observation in April, 1896. Fourteen months before she had noticed an enlarged gland on the right side of her neck, and her voice became husky. She had attacks of violent paroxysmal cough, after which the sputum, which was generally moderate in amount, would be streaked with blood. There was some pain in swallowing, and a constant feeling of discomfort in the region of the larynx. There had been some loss of weight, ten pounds in a year, but no marked decrease of strength. The general condition was on the whole pretty good. Six weeks ago a tumor was discovered springing from the right vocal band. At the time of my examination this tumor, which concealed and seemed to involve all but the anterior third of the right vocal band, was somewhat pale in color, and had an irregular surface. The ventricular band, the aryepiglottic fold, and the epiglottis on the corresponding side, were thickened, and the right side of the larynx was motionless. The left side was normal. I removed a piece of the projecting tumor, under cocain, with Mackenzie's laryngeal forceps, and the specimen was pronounced an epithelioma. The patient was at this time seven-months pregnant, and it was decided to postpone operative interference. After her confinement, which was free from complication, she made very marked improvement. The slight sense of dyspnea, which had previously existed, entirely disappeared. Her voice was regained sufficiently to enable her to sing in a low tone. A few weeks later she had an attack of pleurisy, with effusion on the left side, from which she seems now to have entirely recovered. Her present condition is one of comparative comfort. The laryngeal tumor is reported not to have increased in size very much during the past year. The enlarged cervical glands are still noticeable, but are much smaller than they were a year ago. At times she suffers a great deal of pain in swallowing, and coughs immoderately. There is no fetor to the breath, and the secretions from the larynx are not excessive. When lying in certain positions she suffers some inconvenience from obstruction to respiration, but otherwise she has no dyspnea. Her pain has never been severe enough to require anodynes, except the occasional use of a four-per-cent. solution of cocain as a laryngeal spray. The question of operative interference was left to the decision of the patient herself and of her husband, who is a physician, and the conclusion seems to be that she is quite as well off today as she would have been without a larynx, had she survived the operation.

In spite of the fact that many of us may have had the unhappy experience of being misled on certain occasions by the microscope, these cases served to impress upon me the importance of subjecting all of our laryngeal neoplasms to microscopic examination, more especially those occurring at and after middle life. Otherwise, in most cases, we have no means of making a positive diagnosis of incipient cancer of the larynx. In the absence of definite microscopic testimony, we shall be forced to reach an opinion by exclusion. Late cases are generally characteristic, but the early stages of malignant disease present no objective appearances which may be safely relied upon for diagnosis. The development of the Röntgen ray as a diagnostic resource is awaited with interest. It seems reasonable to expect that it may eventually give us valuable information as to the extent of the infiltration and the limits of a diseased area.

With regard to laryngectomy, I am disposed to class myself with the opponents of *complete* extirpation. When the disease has so far advanced as to demand such radical procedure, the case is well-nigh hopeless. By the time the whole larynx, or a large part of it, is involved, the disease has presumably disseminated itself far beyond the boundaries of any feasible operation. The involvement of glandular structures, remote as well as in proximity to the larynx, renders recurrence at the site of operation or elsewhere almost inevitable. No doubt the statistics of laryngectomy are becoming more favorable with improvement in technical details of the operation and of after-treatment. Nevertheless, it seems to me that in order to reach a just conclusion as regards extirpation of the larynx in a given case, we have to consider another question than that of statistics, namely, the temperament of the individual upon whom it is proposed to operate.

To a person of stolid, phlegmatic disposition, the loss of the larynx is of much less consequence than to one of sensitiveness and refinement. To the latter deprivation of the power of speech becomes almost insupportable, and the kind of speech without a larynx acquired by some of these unfortunates, as in Cohen's famous case, in one more recently reported by Ward,[1] and in several others, or that provided by the various ingenious substitutes for the normal larynx, offers very poor consolation. It has been my misfortune to observe several cases of laryngectomy in which the patient lapsed into a morbid mental condition bordering upon suicidal melancholia. Whenever the question of operative interference arises it would seem wise to take this matter into consideration.

My object in briefly reporting these three cases is first to call renewed attention to the difficulty of making a diagnosis from the clinical history and the objective appearances, and to insist upon the importance of the microscope as an diagnostic adjuvant even in apparently innocent cases; in the second place, to remind you of the possible concurrence of several pathologic conditions; and finally, to protest against indiscriminate operating in malignant disease of the larynx.

A NOTE ON THE PATHOLOGY OF COMPLETE OR ANNULAR PROLAPSE OF THE URETHRAL MUCOUS MEMBRANE IN WOMEN, WITH THE REPORT OF A CASE.

By WM. S. BAGOT, M.D.,
OF DENVER, COL.;
GYNECOLOGIST TO ST. LUKE'S, ST. JOSEPH'S, AND THE ARAPAHOE COUNTY HOSPITALS; CONSULTING SURGEON TO THE COTTAGE HOME LYING-IN HOSPITAL.

In a former communication on "Complete or Annular Prolapse of the Urethral Mucous Membrane in Women,"[2] I reported three cases, and stated that the results of the microscopic examination of the last two cases (this unfortunately was omitted in the first) would tend to confirm the opinion that the cases described as "complete prolapse of the urethral mucous membrane" are rarely, if ever, instances of true primary prolapse of this membrane, but that is secondary to some neoplastic change in the membrane, the most usual being, according to the investigations of C. Ruge and Martin, an angioma, In further support of this statement I now report the following case which has recently come under my observation:

Miss G., aged fifty years, a nullipara five years past the menopause, came to me complaining that during the previous six months she had been suffering from intermittent hemorrhages from the genitals. The bleeding on several occasions had been quite profuse, amounting once, in her opinion, to almost a pint. During the intermissions she had noticed a profuse watery, sanious discharge which of late had become very offensive in odor. Urination recently had become more frequent and caused considerable scalding in the neighborhood of the external meatus both during and after the act. For two years she had noticed a slight swelling occupying the orifice of the vulva, but, as it did not give rise to any serious inconvenience, she did not consider it necessary to consult a physician. Recently, however, the tumor had increased in size and her sufferings had become so marked that she was compelled to seek relief.

Examination revealed a tumor about the size of a large English walnut, of deep purple color, projecting between the labia majora and filling up the vulvar orifice. About the center of the tumor at its most projecting point was situated the external orifice of the urethra, widely dilated so that the little finger could be passed through it for the distance of about half an inch. On the posterior aspect, some little distance below the urethral opening, was a small gangrenous area about the size of a dime. The growth was removed in the following manner: A circular incision was made through the mucous membrane around the base of the growth. Then deciding that it would be necessary to remove a portion of the mucous membrane of the urethra also, as the diseased condition affected it, another incision, commencing at the most dependent point of the first and involving only the mucous membrane, was carried up along the anterior wall of the vagina in the long axis of the urethra for the distance of half an inch. The urethra was now dissected out, as in Gersuny's operation for incontinence, almost to the neck of the bladder. The tumor was removed, with about a third of the urethra proper, and the cut surface of the urethral mucous membrane drawn down and fixed externally by means of interrupted sutures of fine silkworm gut. The operation was completed by closing the longitudinal incision in the anterior vaginal wall with several sutures of the same material. A soft rubber catheter was inserted and allowed to remain during the first two days after the operation. The sutures were removed on the seventh day, when complete union was obtained, and the patient left the hospital two weeks later, since which she has had no further trouble.

Microscopic examination of the growth proved it to be an angioma. Its free surface was covered by an epithelium similar in structure to that normally found in this location. From this epithelium somewhat dilated and hypertrophied glands passed down into the subjacent tissues. Beneath the epithelial covering and surrounding the glands was considerable round-celled infiltration of an inflammatory character.

INTUSSUSCEPTION IN AN INFANT SIX MONTHS OLD, WITH DEATH IN TWENTY-FOUR HOURS.[1]

By WM. FITCH CHENEY, M.D.,
OF SAN FRANCISCO;
ADJUNCT TO THE CHAIR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN, AND CHIEF OF THE CHILDREN'S CLINIC, COOPER MEDICAL COLLEGE.

BABY A. was born March 29, 1896. He had but little difficulty in making his entrance into the world, and the only trouble he found in life was that his mother could not supply him with enough to eat. But this lack was repaired by cow's milk, modified by the Rotch formula, and on this food Baby A. steadily gained in size and weight, until an accident occurred which suddenly and tragically put an end to his life.

This accident took place on September 26th, when the baby was just six months old; and it came like a thunder clap from a clear sky. At nine o'clock on the morning of that day, he took his food as usual, about four ounces in amount; at twelve o'clock he had a natural and free evacuation from his bowels; but at two o'clock he commenced to cry as if in pain, though previously playful and contented all day. He cried incessantly about an hour and a half, then vomited freely. He continued to vomit at intervals all the afternoon and evening, and between times appeared to be nauseated and in pain. He refused all food until late in the evening, when he was persuaded to drink part of his bottle of milk; but almost immediately afterward this was ejected.

So the nausea, vomiting, and whimpering continued without other symptoms, until one o'clock on the morning of September 27th, when the baby had a peculiar passage from the bowels. This was the first passage since noon, and was peculiar in that it contained a small amount of blood, considerable water and some flakes of mucus, but no fecal matter. Now for the first time the parents became sufficiently alarmed to summon a physician. I saw the baby about 2 A. M., and was at once shown the napkin containing the bloody discharge. The passage was not large—could not have been over an ounce in amount, and was pale red in color, indicating that only enough blood had intermingled with the watery evacuation to give it a tinge. The baby at that time was apparently not in great pain, but fretful and moaning occasionally, sometimes dropping asleep, sometimes perfectly quiet when awake. He made frequent attempts at vomiting without anything coming up, but there was no straining or tenesmus as if the bowels were inclined to move. His pulse was 140, his temperature per rectum 102½° F.

Look now at the differential diagnosis of this case. Except the bloody passage from the bowel, every symptom spoke of an attack of acute gastric indigestion. The sudden onset with pain, followed by vomiting; the continued retching and nausea, with pain and refusal of food; the moderately elevated temperature and high pulse-rate, were all characteristic of acute indigestion. Furthermore, the history supported this diagnosis; for the last food given and retained, at nine o'clock on the morning of September 26th, was part of the amount prepared nearly twenty-four hours before. The weather at that time was quite hot, and it appeared more than likely that the food had undergone fermentation before the baby took it, and so had caused the symptoms present. On the other hand, the passage containing blood at once created suspicion of intussusception; a suspicion strengthened by the mode of attack—acute onset with pain, followed by vomiting, and with continued pain and nausea as the prominent symptoms. With this suspicion in mind I carefully palpated the abdomen, but could find no tumor, and made digital examination of the rectum, but could detect nothing abnormal there. The diagnosis certainly lay between these two conditions—acute indigestion and acute intussusception; one very common, the other rare; one due to a cause here manifestly present, the other without any cause apparent in the history of the case; one comparatively simple and benign in its course, the other with an outlook most forbidding. Without certainty to guide me on either hand, I accepted the explanation most probable and made a diagnosis of indigestion. I prepared and gave an enema of starch water containing twenty drops of paregoric, with instructions to repeat this in four hours; applied a mustard paste to the abdomen, and ordered all food to be withheld absolutely and no drink to be allowed but egg water.

At nine o'clock the next morning I found to my surprise that the baby was decidedly worse. He had had but little respite from pain, in spite of the opium, and had kept up almost constantly the nausea and retching, without ejecta. There had been no further passage from the bowels, of any sort. His pulse was now too quick and thready to be counted readily; his temperature per rectum was 105½° F.; his eyes were sunken and his pallor marked. Again careful examination by abdomen and rectum were made, but no tumor could be detected. Still of the opinion that the case was one of indigestion, I explained the alarming symptoms to myself as those of intoxication, due to the fermenting and poisonous milk locked up in the bowels. I have seen similar effects produced by this cause before and since this case. Acting on this theory, I at once changed my plan of treatment, stopping the paregoric and ordering instead one-tenth of a grain of calomel every hour until the bowels moved. At the same time, realizing the gravity of the situation, I asked for consultation, and permission being granted, agreed to see the baby again with a consultant in the afternoon.

It was one o'clock before I returned to my office, and there I found the father of the infant waiting for me. He stated that the baby had just had another bloody passage, and in proof showed me the napkin he had brought along. Convinced by this that the case after all must be one of intussusception, I hastened back with him to his home. There had been a third passage of blood and mucus, without fecal matter, just before we arrived, and when we reached the house the baby's condition was critical; the pulse was imperceptible and the countenance showed that death was imminent. Even at this time I could make out no tumor by abdomen or rectum, but the repeated bloody discharges from the bowel left no doubt as to the diagnosis. Faithful efforts were now made to reduce the intussusception by high injections into the bowel, but it was too late. The baby died at 2:45 P. M., barely twenty-four hours after he was taken ill.

---

[1] Read before the San Francisco County Medical Society, April 13, 1897.

Permission to open the abdomen was granted by the parents, and I made this partial autopsy next day at noon. I found the ileum pushed down into the cecum, through the ileocecal valve, for three inches of its extent, and so firmly caught there that considerable force was required to release it. Above the point of obstruction there was a quantity of thin, pearly fluid, containing flakes of coagulated casein.

Intussusception is not infrequent in infancy; in fact, statistics show that of all cases occurring under ten years of age, one-half occur between the fourth and the ninth months of life. This is explained by the anatomic peculiarities of the intestine in infancy; its walls are thin and lax and its mesentery flabby so that more motion is allowed than in adult life. Yet these conditions after all act only as a predisposing cause, and the exciting cause is usually obscure. Pre-existing intestinal disorders accompanied by straining, such as constipation or dysentery, are apt to bring on intussusception; but the great majority of cases, like the one reported, occur in infants whose previous health was apparently perfect. The only explanation is therefore this: because the intestinal tube is lax and flabby, it is easy for one part to be carried down by peristaltic action inside the part beyond, especially when the part beyond is wider in its lumen, as at the junction of small and large intestine; and about seventy-five per cent. of the cases of intussusception in infants occur at the ileocecal valve. In the case reported it seems likely that the food had undergone fermentation before its ingestion, as explained; and that this irritating food, by increasing the force of peristaltic movements, was the immediate cause of the accident. No doubt indigestible food, acting as an irritant, and so setting up unusual peristaltic waves, is a common cause of intussusception in infants.

The prognosis of this affection in infants is always grave in the extreme. The most favorable statistics place the mortality in cases under one year of age at sixty per cent. It is unusual, however, for death to occur so early as in the case here reported. In forty-nine cases collected by J. Lewis Smith and recorded in his work on "Diseases of Children," only two died in twenty-four hours from the onset; and out of ninety-two fatal cases collected by L. Emmet Holt and very recently reported in his work on "Diseases of Children," there were only two that died in twenty-four hours. The average duration of fatal cases is three days, and the great majority die within a week.

Thus it is seen that intussusception in infants generally occurs without warning and is terrible in the suddenness with which it kills. What is to be done for it must therefore be done quickly, and this implies prompt recognition of the trouble. The typical and diagnostic symptom is the passage from the bowel of bloody liquid and mucus, containing no fecal matter. Another time, on the first appearance of such a discharge from an infant's bowels, with a history of vomiting and pain preceding, I shall at once treat the case for intussusception, without waiting for a tumor, or tenesmus or other classical signs. The only treatment of any use is mechanical. The invagination must be released by pressure from below. This can frequently be accomplished by injections through the rectum; but if these fail, the only resort is laparotomy and manual reposition.

Injection is to be made with a fountain syringe and warm water. The infant should be anesthetized, the hips elevated 45° and the syringe-bag raised well above the body to secure sufficient pressure. It has been estimated that the elevation of the receptacle each two and a half feet will add one pound pressure to each square inch. If the bag is held five feet high, as usually advised, a pressure will thus be exerted on the bowel of two pounds to the square inch. This pressure should be kept up for twenty to thirty minutes, the fluid meanwhile being retained in the bowel by pressing the soft parts tightly around the syringe-nozzle. If not successful the first time, it should be repeated once or twice, but not more, after allowing an hour's interval for rest. There is nothing, as a rule, to show at once that reduction has been effected; only by the occurrence of a normal evacuation from the bowels shortly after injection and by relief of the general symptoms, is proof furnished that the obstruction has been removed.

Laparotomy is indicated as soon as a thorough trial of reduction by injections has proven unsuccessful. The history of the case reported shows the necessity for despatch. Hours are precious, and no time should be lost in resorting to operation when other measures have failed. The earlier it is performed, the greater the hope that it will succeed. But the most distressing obstacle in the way of success by any method of treatment, is the failure to make a correct diagnosis until it is too late.

MEDICAL PROGRESS.

Manual Rectification of Faulty Head Positions.—FRY (*Am. Jour. of Obstetrics*, March, 1897), in a paper read before the Washington Obstetrical and Gynecological Society, advocates in the strongest terms the manual rectification of faulty head positions. "Let us recognize the fact," he says, "that tardy labors can be terminated speedily and successfully by other means than by forceps."

Special reference is made to cases of occipito-posterior and other faulty head positions, where the woman is suffering from impaired vitality or chronic disease, in which case a prolonged second stage, with forcible contractions, is much to be dreaded. Numerous rules are given for the rectification of the various malpositions, differing according to the degree of descent of the head, *viz.*, above the superior strait, in the pelvis, or at the outlet. Certain rules are common to all cases. The patient should be anesthetized, placed on the edge of the bed, with thighs and legs flexed, thorough aseptic and antiseptic precautions observed, and the hand introduced during the absence of a contraction. All manipulations above the brim must be accomplished in the interval between the contractions, while those in the pelvis, or at the outlet, during a contraction.

1. When above the brim or slightly engaged:

In occipito-posterior positions the head should be raised by upward pressure on the forehead, which also causes flexion, then grasped and rotated forward.

In cases with small heads and roomy pelves it is possible sometimes to change occipito-posterior into mento-anterior, and mento-posterior into occipito-anterior positions. Brow and transverse presentations are treated on the same principle. Face presentations are changed by raising the head, pushing up the forehead, and drawing down the occiput.

2. When within the pelvis:

Occipito-posterior or face presentations, by the aid of anesthesia and posture, either the knee-chest or Trendelenburg, the head may be disengaged and treated in the same way as above. In desperate cases he advises symphyseotomy to allow room for the necessary maneuvers to change it into a vertex position.

3. When at the outlet:

The manipulations are the same as when well down in the pelvic cavity, though with much greater hopes of success.

Surgical Intervention in Peritonitis Occurring in Typhoid Fever.—Before the Academy of Medicine, Paris, DIEULAFOY, as reported in the *Gaz. Hebdom. de Méd. et de Chir.*, rejects the division of peritonitis occurring in typhoid fever into peritonitis by *perforation* and by *propagation*. He denies the existence of the latter, considering that sufficiently careful search will in every case reveal some minute fissure in the intestinal wall, a ruptured infected gland, possibly a ruptured gall-bladder, or a perforation of the appendix vermiformis. This last cause, which is by no means so rare as one might suppose (15 cases in 133 autopsies for perforation in typhoid, according to Nacke), is not the ordinary appendicitis with rupture, but is a true typhoid perforation due to alteration of the lymph-follicles of the appendix, just as perforation of the small intestine results from an exactly similar alteration of the lymphoid tissue in Peyer's placques.

Besides this true typhoid appendicitis, there also occurs in connection with typhoid fever the usual form of appendicitis, which may be called a *paratyphoid* appendicitis, and which has not been sufficiently studied, but which is marked by an acute attack, and which has the various well-known terminations in localized or general suppuration.

The outlook for these cases of perforative appendicitis, both typhoid and paratyphoid, is much brighter than that of intestinal perforation. The chief point in differentiating them is the fact that they cause a rise of temperature, and not the sudden drop which occurs in intestinal perforation. Dieulafoy also places reliance upon the occurrence of hiccough as a symptom of commencing peritonitis, especially if it first makes its appearance in the third week with abdominal pain, nausea, and an increased meteorism. There are, however, a few rare cases in which hiccough occurs in typhoid fever as a purely nervous phenomenon independent of peritonitis.

If perforation occurs, measures for relief such as ice, opium, etc., are usually of no avail. In considering the advisability of surgical treatment, it is first necessary to separate the appendical from the intestinal cases. In the former the results of operation are excellent; in the latter the diagnosis is often obscure. One cannot always be sure perforation has occurred; yet delay of a day or so, if it has occurred, will take away what little chance for recovery there may be. Statistics so far teach little. Lejars collected 25 cases operated upon with 6 recoveries, but it is doubtful if 3 of these are properly considered under the subject of the discussion. One patient operated upon by Routier lived some days and then died from a fresh perforation. Autopsy showed that the sutured perforation had cicatrized, so that surgical interference is capable of cure if no new perforation supervenes.

Chronic Bronchitis of Children Treated Surgically.—CHAUMIER says (*La Presse Méd.*, April 24, 1897) that the chronic bronchitis which is so often seen in children is due either to adenoids in the nasopharynx or to a chronic catarrh of that region without the vegetations. The treatment indicated is, therefore, ablation of the tonsils, and destruction of the adenoids with a galvanocautery. Granulations should be scraped and burned away.

THERAPEUTIC NOTES.

To Allay Vomiting in Cholera Morbus.—

℞	Creosoti	aa . . m. ii
	Ac. hydrocyanici dil.	
	Mucilag. acaciæ	f. ʒ ss
	Aquæ	q.s. ad ℥ i.

M. S. One dose.—*Packard.*

For the Headache Dependent upon Ovarian Disease.—

℞	Ammonii bromidi . . .	ʒ vi
	Ext. hydrastis fl. . . .	℥ ss
	Tr. gentian comp. . . .	℥ iss
	Aquæ	℥ iv.

M. Sig. A dessertspoonful three times a day.—*Sinkler.*

A Case of Tetanus Treated with Subcutaneous Injections of Corrosive Sublimate—Recovery.—In a marked case of tetanus in a boy aged nine, HENDLEY (*Brit. Med. Jour.*, January, 1897) after trying all the various methods of treatment, injected subcutaneously into the patient's buttock one-tenth-grain doses of corrosive sublimate, twice daily. After the first two injections the spasms markedly decreased in both frequency and severity, and after eleven doses the paroxysms had entirely ceased, and the recovery took place fairly rapidly. Small doses of chloral hydrate were also used throughout the disease.

Inhalation of Formalin in Catarrh and Other Diseases of the Respiratory Tract.—According to GREEN (*Brit. Med. Jour.*, January 23, 1897) the most rational treatment of catarrh, and many other diseases of the respiratory tract, is by the inhalation of germicidal remedies. The best results have been obtained with the vapor of formalin; one or two drops being placed inside a Jeffery's respirator. Green also strongly advises its use in the early stages of tuberculous disease of the lungs, together with the ordinary tonic, hygenic and dietetic treatment. Under its use he noted a decided improvement in the patient's condition, and a marked decrease in the tubercule bacilli, and other bacteria in the sputum. For inhalation in acute cases the formalin should be diluted with water as the undiluted vapor is too stimulating.

The Value of Sterilized Milk.—It is claimed by scientists that the sterilization of milk not only destroys the pathogenic bacteria but also many beneficent micro-organisms. BARTON (*Brit. Med. Jour.*) thinks that in view of the enormous saving of infant life since the introduction of milk sterilization an opposite view should be taken. After carefully studying the subject he makes the following statement:

1. Completely sterilized milk, if administered without any fresh food, will undoubtedly sooner or later produce scurvy.
2. Milk that is raised to the boiling point, or better, to within two degrees of the boiling point, and maintained there from five to ten minutes, is "comparatively" sterilized, and will never produce scurvy, and is almost free from pathogenic organisms.
3. Completely sterilized milk, if administered at once in perfectly clean bottles, spoons, or cups, can be relied upon as being free from any pathogenic micro-organisms.
4. The heating of milk alters very little, if at all, its nourishing qualities.
5. All kinds of sterilized milk, if free from added chemicals, can become foul as quickly, if not more quickly, than ordinary fresh milk.
6. All sterilized milk that is put into hermetically sealed vessels, and which can keep fresh in them for many days, will produce scurvy unless some fresh food is administered daily.
7. Milk that is boiled directly over a fire will undoubtedly cause constipation. If the milk be placed in a vessel which stands in another vessel containing water, and the water be brought to the boiling point, its antiscorbutic properties are not lost, and it does not cause constipation.

Plea for Less Restricted Diet in Typhoid Fever.—To mitigate the evils of extreme emaciation, feebleness, and prolonged disablement, BARRS (*Brit. Med. Jour.*, January, 1897) urges a diet of solid food whenever the patient is able to take it and expresses a desire for it, even if the temperature curve is above the normal and the bowels are acting too frequently. If the stomach is digesting, the proper kind of solid food will reach the typhoid lesions in the same state of fluidity as would milk; if the stomach is not capable of digesting simple solid food, the patient will have no appetite, and it would be foolish and cruel to force solids upon him.

He believes a majority of typhoid patients die from cardiac failure, lung complications, and other devastating effects of general infection, against which the patient can set only such powers of resistance as he possesses, and which will be more or less effectual according as his general nutrition is maintained by good food. The conditions for healing in the small intestines are the same as for any of the external parts of the body, and no surgeon would expect to see wounds undergo repair in the shortest possible time in a patient living on fluid diet alone.

The Uses of Suppositories in Children.—Owing to the sensitiveness of the digestive tract in children, and the ease with which its condition may be disturbed by medication, a writer in *La Médicine Modérne*, April 28, 1897, makes a plea for the more extensive use of medicated rectal suppositories. The medicine in these suppositories must be in a state capable of rapid and complete absorption, and the vehicle also must be considered. Cocoa butter does not remain sufficiently long *in situ*. The ideal vehicle is found in a mixture of gelatin and glycerin, recommended by Chaumel. To take a practical illustration: In the case of a nervous, excited child, a suppository containing cocain or antipyrin is introduced, and in a short time its calming antispasmodic effect is produced—both systemically and locally at a portion of the intestinal tract where irritation often exists—and without disturbing in the least degree the stomach and intestine.

Kryofin—A new Antipyretic.—In the *Deut. Med. Wochenschrift* for April 22, 1897, EICHHORST describes his experiments with a new antipyretic called kryofin. Chemically, this drug is closely allied to phenacetin. It occurs as white, odorless, tasteless crystals, soluble in 52 parts of boiling and 600 parts of cold water. The solution has a sharp, bitter taste. The usual dose is 7.5 grains, and the antipyretic effects of this amount are greater than those obtained by 15 grains of phenacetin. No unpleasant symptoms have been observed to follow its use. In addition to its antipyretic action, kryofin has been found to have an analgesic power, and is used with benefit in sciatica and in alcoholic neuritis. In acute and chronic articular rheumatism it failed to relieve the pains.

A Physician's Method of Inducing Sleep.—In the *Chicago Medical Recorder* for April, 1897, LEARNED tells how he has been able to overcome insomnia. The respirations are reduced from 18 to about 12 per minute, made full, deep, and regular, and the attention is concentrated upon them. During this time the head is raised from the pillow a half inch or so and kept in that position until the sustaining muscles are exhausted. This usually occurs after fifteen or twenty respirations. The head is then lowered, the muscles of one leg made rigid, and the foot raised. When the leg becomes tired the same process is repeated with its fellow, the respiratory counting being kept up. The body is then turned on the back or the other side, and without loss of time head and feet are elevated as before. In a short time fatigue becomes so well marked that the brain is glad to "let go" and sleep ensues.

This method has one drawback. It is a continuous effort and is, therefore, not attractive for the indolent. To be successful no rest must be allowed at changes of position.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, JUNE 5, 1897.

THE SEMICENTENNIAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

IT has been said that for a nation to feel that it has a past and a history is a wonderful encouragement to the growth of its moral forces. What is true of nations is true also of associations. The American Medical Association has now reached and passed the golden milestone of its existence. That it has a past and a history of which its members may be justly proud was convincingly presented in the brilliant address of the President, Dr. Senn.

Great achievements and a noble record, however, increase the responsibility of the present. Each annual meeting is an epoch-making event in the history of the Association, and it therefore becomes a pertinent question to inquire what this semicentennial meeting has contributed that is worthy of the organization and of the event. Naturally, the anniversary feature has been prominent. It was a time for reminiscence, for mutual congratulation, for recalling the achievements of the past and forecasting the future. Much time was spent in this agreeable way, and with apparent satisfaction. Dr. Senn presented an exalted picture of the American medical education of the future, and of the rapidly improving institutions for medical education that were destined, even in this generation, to become the finest in the world and to attract students from nations now supposed to be the centers of medical progress. In all fairness, his prediction seems to find justification in the tendency among rival schools to consolidate their resources and in the generous appropriation of large sums of money to build, equip, and endow pathologic and bacteriologic laboratories.

Dr. Flint's Address on Medicine was a thoroughly scientific paper, and a vigorous reminder of the fact that the Association numbered in its membership men capable of conducting the most original scientific investigations and making important physiologic discoveries in unknown fields. It will doubtless prove somewhat of a surprise to our German friends to learn that they have but recently been rediscovering a physiologic product originally discovered and named by an American thirty-five years ago. The importance of consulting American medical literature was thereby also emphasized.

The brilliant contributions of American Surgery to the world's storehouse of knowledge was graphically portrayed by Dr. Keen in the Address on Surgery—and the presence of the venerable founder of the Association Dr. N. S. Davis and his active participation in the anniversary proceedings was a feature of unusual interest and suggested the thought that the sturdy founder typified the stanch material of which the Association was composed.

The Rush Monument Fund now seems in a fair way of being completed in a reasonable time. Small contributions from the many is far better than larger subscriptions by a few. As Dr. Wood said in his eloquent appeal for opposition to the Antivivisection bill now before Congress, what is needed is individual personal effort on the part of the humblest member of the profession and the object is accomplished. Set the machinery in motion to promote this in State, county, and town societies and there is no reason why the complete fund shall not be realized before the next annual meeting.

The attendance was greater than of any previous meeting in the history of the Association and the interest manifested in the scientific and public exercises was gratifying to a high degree. Philadelphia surpassed herself in the hospitality extended, and her guests were made to feel that she is indeed a city "which has the minimum of tenements and the maximum of homes exhaling an air of hospitality.'' Luncheons, receptions, and dinners abounded on every day and on every hand. Not the least appreciated among the entertainments was the theater-party given by the publishers, Messrs. Lea Bros. & Co., on Thursday evening, the size of which was limited only by the seating capacity of the theater. For a period covering four generations it has been the privilege of this house to enjoy the closest relations with the members of the medical profession. It is needless to say that the *entente cordiale* has at least not been lessened by this act of generous hospitality.

THE CONTROL OF VENEREAL DISEASES.

The increase of gonorrhea and syphilis among the British troops in India has recently been noted in these columns. How the problem presented will be dealt with by the British Government does not yet appear, but the question is exciting continued interest both in the lay and medical press, and those who are strongest in their opposition to the Contagious Diseases Acts still admit the necessity of some kind of remedial legislation. As stated in a previous article their objection to this law aside from sentiment is based upon the fact that the most careful examintion of a woman sometimes fails to show her capacity as a source of infection. It is also suggested that when the number of prostitutes is greatly reduced by the retention in hospital of those found to be contagious upon examination, disease among the men increases because the women receive so many in one night that they infect each other through the medium of her person even though she herself escapes contamination. To these objections must be added the great danger of clandestine prostitution which exists even under the most perfect legal system, and to which is ascribed a large part of the cases of syphilis which occur in Paris, Berlin, and other cities, where prostitutes are registered and periodically inspected.

Notwithstanding these objections to governmental regulation the fact remains that venereal disease is many times more prevalent in the British Army than it is in any of the Continental armies where this system is the rule. Nor can this be explained by saying that the general health of the soldier has been neglected. Special attention has been given to athletics, exercise, recreation, etc.—in short to the development and maintenance of a strong physical and moral condition of the army. General sickness and drunkenness have decreased while venereal diseases have increased. While agreeing with the advocates of official inspection to the extent of regarding syphilis and gonorrhea in the light of contagious diseases, and admitting the desirability of preventing those afflicted with these troubles from communicating them to others, it is impossible to believe in the light of past and present experience that inspection and regulation will accomplish all that is desired. Two remedies alone seem able to remove this scourge. One is the absolute prohibition of women within the camp area—a remedy so drastic is not likely to be advocated in any army, least of all in a British army; for whatever may be said of the religious character of the English people, among the men in the classes from which the soldiers are drawn, morality is not a strong point. Still this plan would only put the men in the army upon the same footing as the men in the navy during long cruises.

The other remedy is to allow a soldier to marry and take his wife with him as far as circumstances will permit. This would necessitate a great increase in the pay roll, would very nearly double, apparently, the expense to India of English occupation, and for financial reasons the plan probably stands absolutely no chance of adoption. Still, it may be worthy of careful consideration whether it will not be cheaper for the English nation to submit to additional expense than be overwhelmed by this wave of venereal disease which threatens to spread over England through the infecting agency of her returning soldiery. Whether other considerations would render it impracticable it is impossible to say. Certainly matrimony has not prevented men from rendering acceptable service as soldiers in time of war and, *a priori*, the same may be true in time of peace.

ECHOES AND NEWS.

Smallpox in New York.—The report of smallpox since the outbreaks on March 1st records forty-six cases.

Skiagraphs Not Accepted as Evidence in Court.—Judge Hutchinson refused recently to permit a series of skiagraphs to be used as evidence in a damage suit on trial in his court.

Queen Victoria Vaccinated.—Among the many interesting experiences of Queen Victoria recalled by the approaching celebration is the fact that she was the first member of the English royal family to be vaccinated.

Illinois Vaccination Bill Killed.—By striking out the enacting clause, by a vote of 27 to 10, the Senate of the Illinois Legislature killed the bill providing for the compulsory vaccination of school children in that State.

Women Receive Medical Diplomas.—The twenty-ninth annual commencement of the Woman's Medical College of the New York Infirmary for Women and Children was held May 27th. Sixteen young women were graduated.

Medical Victims of the Paris Disaster.—Of the four men who lost their lives in the disaster at the Bazar de la Charité two were members of the medical profession. At the request of the Academy of Medicine a solemn requiem service was held at the Madeleine on May 15th for the doctors and wives and children of medical men—seven in all—who perished.

Extraordinary Bone Grafting.—A case of bone grafting is reported at one of the hospitals of Buffalo, N. Y., in which five inches of a live sheep's bone has been inserted in a man's leg to replace part of the tibia which had been crushed and destroyed in an accident. The process of attachment and growth is being watched with no little interest through the instrumentality of the fluoroscope.

The Case of Beatty versus Cullingworth.—It is announced that this case is to be re-opened by an appeal to the House of Lords. In commenting on this the *Medical Press* says: "This step is much to be regretted, and the wisdom of those who are finding the money for this further litigation is open to serious adverse criticism. It may be doubted if any single occurrence during the last generation has done more than this trial to strain the amicable relations that should exist between the medical profession and the nursing community."

Medical School Inspection in New York.—The necessity for this work is constantly attested in the weekly reports of the inspectors. The following report has been made for the week ending May 21st. Out of 4510 male and female children examined in the primary departments of grammar schools, primary schools, parochial schools, American Female Guardian Society, and Children's Aid Society, 450 were excluded. There were 5 cases of measles, 8 of diphtheria, 2 of scarlet fever, 1 whooping-cough, 7 mumps, 44 contagious eye diseases, 354 parasitic diseases of the head and body, 4 of chicken-pox, and 17 of skin diseases.

Roll of the University-Bellevue Hospital Medical College Completed.—The New York University Council, at a special meeting held May 26th, eighteen members being present, completed the roll of the professorships of the consolidated medical college by the election to full professorships in the governing Faculty of Dr. E. G. Janeway in medicine and Dr. Frederick S. Dennis in surgery. Dr. A. Flint, Jr., was made Adjunct Professor of Obstetrics and Dr. G. D. Stewart Adjunct Professor of Anatomy. The roll of the governing Faculty now contains twenty-one members, while the clinical, emeritus, and assistant professorships number twenty-five.

To Protect School Children's Eyes.—The New York Board of Health, in conjunction with the Board of Education, is about to take practical action to prevent the increase of nearsightedness among school children. It is proposed to appoint a corps of twelve trained oculists, each of whom shall look after a given school district. Their duties will be to examine and watch each child and pass upon its sight. Those with good sight will be given rear seats in the class rooms, and those with poor eyes, places where they will not have to strain to see the blackboards, maps, etc. The arrangement of these and the proper lighting of school rooms will be the objects of their attention.

Children in Asylums,—James O. Fanning, the inspector of the State Board of Charities, has submitted a report to the Board of Inspection of the twenty institutions in the Eastern Inspection District. The purpose of the inquiry was to ascertain the cause of commitment, the reason, if any, for long detention, and, when possible and proper, to secure removal to the care and custody of parents, relatives, or friends, and to inquire into the family history of the children committed to the institutions. The inspectors made 133 visits to institutions, 614 visits to families, interviewed 1579 children, and has effected so far the discharge of 302. The number of removals represents a decrease of about $600 per week in the expenditures of the municipalities named for the support of dependents.

Water in Chicago Schools.—For the first time in over seven weeks the city water was allowed to be used in the public schools of Chicago, it having been shut off by the Board of Health because of its bad condition. It has not improved, but the demand for it became so insistent that the board had to comply. The Health Commissioner declines, however, to take responsibility for the act. His board had ordered the school hydrants equipped with filters, but the Board of Education had refused to buy them, deeming filters of no protection against germs. Then the water was ordered boiled, but the Board of Education refused to do this, because it could not afford the expense. Then the Board of Health shut the water off to the serious inconvenience of the pupils. It has been obliged to yield at last.

Lord Lister.—The British journals are full of accounts of Lord Lister's many honors. One speaks with great satisfaction of the excellence of his maiden speech in the House of Lords, another of his dining with her Majesty the Queen at Windsor Castle, and all of them mention the unique banquet which was to occur on May 26th at the Café Royal, London, at which Lord Lister was to be entertained by all the house surgeons, clinical clerks, and dressers who worked under him at Glasgow, Edinburgh, and London. As an instance of the interest taken in the event it is reported that a former dresser has come all the way from British Guiana to be present, and the oldest of Lister's house surgeons, Dr. Ramsey of Torquay, aged seventy-three, will be present. The father of antiseptic surgery is evidently being appreciated.

The Skeleton of Professor Cope.—Besides leaving his paleontologic collections and most of his fortune to the University of Pennsylvania and its allied institutions, the late Professor Edward Drinker Cope took care that death should not end the usefulness to science of even his mortal tenement. In accordance with the provisions of his will, only a part of his body was cremated. His brain is to be preserved in the Wister Museum of the university, and in the same place his skeleton will silently continue the instruction to which Professor Cope's life was devoted. The relics of the departed teacher are to be prepared by men who knew him well and often worked with him, and near them in the museum the ashes of his flesh will be preserved in an urn standing beside those containing all that was mortal of two other great men devoted to scientific pursuits—Professor Leidy and Professor Ryder.

The Congress at Moscow.—In connection with the International Medical Congress at Moscow a two-weeks' excursion has been arranged to the Caucasus visiting the celebrated mineral baths of which Kislovodsk is the center, and traversing a region notable for its fine scenery. A nominal fee of thirty dollars will be charged. It is announced that guests of the Congress, including ladies, will pay no admission fee but they will not be entitled to the free railway passes from the frontier stations on the Russian lines, accorded to members. Visiting members may obtain hotel accommodations in advance by applying to Professor Chervinsky of Moscow. It is estimated that the cost of rooms will be about one dollar and twenty-five cents per day. A committee of ladies of Moscow has been formed for the purpose of securing comfort and entertainment for the ladies accompanying the members of the Congress.

Chewing Gum Is Interdicted.—In addition to the injurious effects produced by the excessive overstimulation of the salivary glands occasioned by the habit of gum chewing, the act itself is a breach of good manners. Anent the reprimand administered by one of New York's magistrates to the attending policemen for chewing gum in the court, the *Sun* says: "Gum-chewing, although it isn't positively offensive, like tobacco spitting, is the height of vulgarity. It may be tolerable for athletes who have special need of working their salivary glands in order to keep their mouths moist; or it may serve to soothe the nerves of a billiard player in undergoing the strain of a great match. But it distorts the face, gives it a slatternly and careless aspect, and offends the rule requiring people to finish their dinner before rising from the table. Besides, it very often causes the emission of a nasty sound from the gnashing jaws."

Statistics of New York Dispensaries.—In a report recently submitted to the State Board of Charities Dr. Stephen Smith presented the following statistics: "The number of dispensaries in this city connected with hospitals are 31; with churches or missions, 9; having governing boards, 58; under private control, 7; total, 105. In the cases of those with governing boards, which are supposed to exercise a strict supervision, there are only 13 whose boards have made daily visits. The boards of 11 have made weekly visits, of 7 monthly visits, of 2 annual visits, while the board of one has visited only four times since incorporation in 1889, of another only five times since incorporation in 1869, and of another, never. Only 47 have a regular board of officers, 20 have only a president, 2 have no officers whatever. In 67 medical or surgical aid is entirely free, in 16 the intention is to charge a small fee, in 8 aid is accounted paid for by benefit to the students present. In only 7 dispensaries is any record of the names and addresses of patients kept, and in only 33 any record of diagnosis and treatment, while in 21 no record of any kind is kept. The worthiness of a case is decided by investigation (generally superficial) at 44 dispensaries, by mere appearance at 18, and at 6 no questions are asked. At 7 patients are charged ten cents or more, if able to pay; at 3 some charge is made for surgical aid, at 11 something is charged for medicines and dressings, at 2 something for board (if able to pay), at 39 from ten to fifty cents for medicines, and at 3 payments are voluntary. The medical staff renders gratuitous service at 51, at 2 the members receive board and lodging, at 15 they are paid from $25 a month to $1500 a year. Thirty-seven dispensaries have from 1 to 10 medical attendants, 28 from 10 to 25, 6 from 25 to 50, 2 from 100 to 165, and 1, none. The trustees appoint the medical attendants in 24 dispensaries, individuals in 9, and medical boards in only 18. One dispensary replied that the question on this point was a 'fool question.' At 3 mission dispensaries the medical attendants are appointed by the minister in charge. Examination precedes appointment in only 3 institutions. In 10 the number of persons treated ranges from 80 to 100, in 1 from 500 to 1000, in 28 from 1000 to 5000, in 20 from 5000 to 55,000, and the total number treated in 1895 was 837,971."

CORRESPONDENCE.

THE INITIAL DOSE OF TUBERCULIN.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In an article written by me which appeared in the MEDICAL NEWS, May 29, 1897, on the tuberculin test, I am made, through a typographic error, to say "The first injection should not exceed five milligrams, whereas the text should read "The first injection should not exceed five-tenths of a milligram."

As the use of a small initial dose is an essential feature of the method I have employed, and as the injection of so large an initial dose as five milligrams might result in producing very unpleasant symptoms, may I ask you to correct in your next issue this unfortunate mistake?

In order to make the matter plain, allow me also to repeat the following sentence from the original article: "The adoption of an initial dose so small as to guard against the possibility of producing violent reactionary symptoms, and a graded increase of subsequent doses within such quantities as are known never to produce reaction in healthy individuals would seem to afford the best protection against unpleasant results and misleading evidence."

Very truly yours,
E. L. TRUDEAU.

SARANAC LAKE, May 30, 1897.

OUR VIENNA LETTER.

[From our Special Correspondent.]

SERUMTHERAPY OF DIPHTHERIA IN HUNGARY—A CASE OF COMPLETE TRANSPOSITION OF THE VISCERA, AND A CLINICAL DIAGNOSIS OF THE CONDITION—THE COINCIDENCE OF THREE CASES OF COMPLETE TRANSPOSITION — CONTINENTAL AND AMERICAN NURSING AND NURSES—THE SIGNIFICANCE OF A PHYSICIAN'S PHOTOGRAPH.

VIENNA, May 15, 1897.

THE recently published official statistics of serum-therapy of diphtheria in Hungary seem of special interest, coming as they do from a country where the influence of a preconceived judgment, for national or other reasons, was not at work to make the result conform to expectations. Toward the end of 1895 the government decided that all cases of diphtheria treated under its supervision, whether in hospitals or in district practice, should have the advantage of serum-therapy. Some 10,000 cases were treated in this way before February of this year, with a total mortality of 19 per cent. The mortality in Hungary from this disease during the year 1893 was 43 per cent., and during 1894, 43.7 per cent., the statistics being compiled from over 40,000 reported cases. The recent statistics are collected from about ten different districts. A comparison of the results obtained in each of the districts shows that there were no striking differences in the death-rate, but a corresponding improvement as to mortality all over the country. The mortality percentage varies only about 6 per cent. in districts widely separated, and whose inhabitants are living under extremely different circumstances. The highest mortality recorded, 27 per cent., comes, as might be expected and as has been the case everywhere, from the hospitals. It is in the hospitals that the patients are treated who, as a rule, before the attack have lived under the poorest and most unfavorable circumstances, in which the diagnosis has been longest delayed, and in which the treatment could only be applied when secondary infection had already taken place. It is to the statistics of such cases that the opponents of serum-therapy refer in order to justify there opposition. Even with all these disadvantages the serum treatment has effected a notable decrease in the death-rate of hospital cases.

Most of medical Vienna has been amused during the past week at the clinical diagnosis of a case in which the autopsy revealed complete transposition of the viscera. Death was the result of gangrene of the lung. The diagnosis had been made with a great deal of care, and the case had even been the subject of a demonstration at one of the special post-graduate clinics. The heart was very weak, and considerably diseased, and the apex beat was undiscoverable. The presence of huge gangrenous cavities, and of deeply infiltrated surrounding lung tissue, obscured the real condition of affairs in the thorax. The somewhat enlarged spleen was taken for a cirrhotic liver, there being a history of alcoholism, while the almost normal liver was made out to be a much enlarged spleen. The diagnosis in faultless Latin, *hepatitis cirrhotica tumor lienis chronicus*, doubtless sounded better at the bedside than it did when reread in the cold, unsympathetic atmosphere of the section room.

The tendency of even the rarer anomalies to turn up in groups, illustrative, I suppose, of the "innate perversity of inanimate thing," is exemplified by the occurrence of three specimens of complete visceral transposition in the autopsy-room within six weeks. In two of the cases it was noted that the right testicle hung lower than the left, so that the explanation of this peculiarity, for which so many theories have been formulated, would seem to be absolutely dependent on the general conformation and position of the abdominal organs. The appendices on the left would have puzzled an unsuspecting and suddenly summoned medical man in case of inflammation of that highly susceptible evolutionary remnant. As there do not seem to be many cases recorded in literature of removal of the appendix from the left, perhaps some of its susceptibility is in abeyance in its unusual situation. In one of the cases the clinical history seems to show that the subject was right handed. The theory that right handedness generally is due to the greater weight of organs on the right side would seem to require left handedness in these cases. The exceptional "left hander" would certainly help to prove the rule, in the true sense of that much-abused aphorism, if he would but fortuitously and persistently turn up in these instances.

The discussion occasioned some months ago by the appearance in a prominent English magazine of a not very favorable criticism of English nurses, would lead the American abroad to compare Continental nursing and nurses with the English and our own. After all the modern American trained nurse occupies about the same position as her English professional sister. If anything, American nurses come from a better class, have a better preliminary education, and are even more especially trained, and consequently are more trusted and more thought of. Continental nurses, if one may speak in general after having seen French, Italian, and Austrian nurses, are, as a class, not at all what American medical experience of the last few years has made us acquainted with. The work does not seem to be taken up as a profession by those engaged in it as it is with us, and there is a consequent lack of interest in acquiring its necessary details. It is taken up casually because nothing better presents itself at the moment, to be dropped at the first opportunity. Very little serious organized effort seems to be expended in training them in their duties, and they occupy about the position of better-class hospital servants. The contrast is very marked in the position occupied here by the nurse and that which we are accustomed to, and I do not think that it is calculated to make American physicians like their own system less or the European more. The highly specialized training given nurses in the English and American system, and the position of trust that the nurse has come to occupy in consequence, may have given rise to some of the evils that the fair English critic of the nursing system pointed out. The consciousness of professional knowledge may have led some of its possessors into thinking themselves of more importance than they really are. Some may even have taken advantage of the position to entrap a callow doctor, or a susceptible unwary bachelor patient, into putting on the matrimonial halter. But these are not faults that are confined to nurses, and not necessarily connected with the training they receive. Meantime as the result of their training the physician and surgeon finds in them skilled and trustworthy assistants to whose prudence and carefulness he can entrust details of treatment or of preparation for an operation which relieve him of a weight of care. It is only a matter for rejoicing that in consequence of this position of trust the nurse has learned her own worth, and the dignity of her position, and has gained correspondingly in self respect. The hospital servant of the old days, as one sees them here, shows how distinct has been the change for the better from the invasion of professionalism, and one is glad not to have to go back. Perhaps, as in all things medical, the pendulum has swung a little too far in the training of nurses, but the trained nurse may be trusted, like advances generally in medicine, to find her proper place.

Occasionally one finds in the Austrian medical journals advertisements of positions which are open to young doctors and for which one of the requirements demanded in making out applications is somewhat unexpected. Besides asking for his degrees and evidence as to preliminary education and post-graduate experience, the notices require him to send his photograph. The personal appearance of a doctor has always been said to be of a good deal of importance as regards his success professionally in private practice, but this very *naive* admission that it will influence the decision as to his adaptibility for a hospital position is almost amusing in these days of supposedly scientific meidcine. Whether some have not been found who have sent a veritable "counterfeit presentment" of themselves in the shape of a photograph of some handsomer man, as is said to be done under corresponding circumstances in matrimonial negotiations, has not yet come to light, but may be confidently expected. Meantime the day of the personally attractive physician does not seem to be over, and the fortunately gifted ones may rejoice in consequence.

A Point in Electrolytic Epilation.—DUBREUILH (*Bull. Gen. de Thérapeut.*, February 28, 1897), in order to overcome the difficulty experienced in passing the electric needle to the root of the atrophied hairs, cuts all the hairs short in the region upon which he is about to work, and one or two weeks later he passes the needle into the follicle of those which have grown, and are therefore surely alive. The others are drawn out with forceps, and some weeks later, when the new hairs have grown in their places, they are treated with electrolysis. Being then young, they are more susceptible to the action of the electric current.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

The Semicentennial Meeting, Held at Philadelphia, June 1, 2, 3, and 4, 1897.

[Specially reported for THE MEDICAL NEWS.]

GENERAL SESSION.

FIRST DAY—JUNE 1ST.

AFTER the meeting had been called to order by the President, NICHOLAS SENN, M.D., of Illinois, the proceedings of the Association were opened by an eloquent prayer by the Rev. Leverett Bradley, the rector of St. Luke's Protestant Episcopal church, of Philadelphia.

Mayor Warwick was next introduced, and delivered a brief address. "I do not know," he said, in part, "that I have ever extended welcome on behalf of the city of Philadelphia to so many doctors. Philadelphia is the home of medicine; here Gross, Pancoast, Agnew, and Leidy made reputations which became national and worldwide. . . . A doctor is the last man on earth we send for, or want to send for, and although I have heard certain men in health deny both God and the doctor, I know that it is just these men who call most hurriedly for both when they fall ill. Personally, I have the highest regard and respect for the doctor, and I am really glad to see you here; and if I had a full opportunity to express all I think and feel you would see that it would be impossible for anyone to find a heartier and more sincere welcome than this that I give you now."

In the absence of Governor Hastings of Pennsylvania, who was detained in Harrisburg, the address of welcome on the part of the State was given by Charles Emory Smith, Ex-minister to Russia, who, in an address, which was both eloquent and facetious in parts, welcomed the Association to the State of Pennsylvania.

He said that, inasmuch as the Governor was compelled to hold an important surgical clinic to-day in Harrisburg, he had been drafted at the last moment as a substitute, an unprepared but entirely willing one. The nature of the Governor's work was the amputation of a gangrenous legislature, and he was sure that every member of the American Medical Association wished him every success in this dangerous procedure. Mr. Smith's remarks touched on the historical side of the medical profession in Philadelphia, and concluded with a hearty welcome on the part of the commonwealth of Pennsylvania to the members of the Association, wishing every success to their deliberations and the most beneficial results to mankind as their outcome.

DR. H. A. HARE, Chairman of the Committee on Arrangements, made several announcements relating chiefly to the social features of the meeting, and formally announced the program of entertainments for the day, and submitted the report of the committee, which was unanimously accepted.

Following this report the address by the President of the Association, DR. NICHOLAS SENN, was delivered. (See page 725.)

DR. HARE presented President Senn with a gold insignia of his office, and in a felicitous speech conveyed to him the appreciation of the Association of his work. Dr. Hare then moved that an invitation be extended to many foreign visitors now in Philadelphia to attend the meetings of the Association, which motion was unanimously carried.

The report of the Committee on the Rush Monument by A. L. GIHON, M.D., Medical Director United States Navy, was listened to with a great deal of attention. After a glowing tribute to the work, patriotism, and heroism of Benjamin Rush, Dr. GIHON went on to contrast the work accomplished by the Homeopathists in erecting a magnificent statue to Hahnemann, with the unfruitful efforts of the Regular School of Medicine to commemorate the name of "America's greatest physician" with a fitting memorial, and emphatically pointed out that, while a small body of the deluded followers of Hahnemann had in four years subscribed $75,000 for their purpose, the mass of the regular profession in America had in twelve years succeeded in raising only a trifle over $4000.

The committee had finally exhausted its own resources, and it now appeals to the Association to determine at once and definitely what further steps are to be taken in the matter—whether the erection of a modest bust of bronze, such as is warranted by the amount of money in the committee's hands, or an appropriate memorial, such as the name of Rush and his claim to national recognition demand. After the thanks of the Association were tendered to Dr. Gihon for the report, Dr. Cutter of New York moved that $1000 be appropriated annually by the Association until the requisite sum for the completion of the monument was obtained. Dr. Cutter's motion was withdrawn, however, after an amendment offered by Dr. Graham of Colorado that the Association immediately raise $100,000 for the purpose, and pledging Colorado to raise the first $2000 for the fund. Dr. Graham's amendment stirred up the greatest enthusiasm, and resulted in subscriptions on the spot of $2000 each from the States of Ohio, Missouri, Illinois, Pennsylvania, and New York; and in personal subscriptions of $100 each from Drs. Russ, Cutter, Hall, Ferguson, Wiggin, Jelks, Holt, and Herrick, besides the promises of nearly every president of the State societies to co-operate in the movement, according to their ability to contribute to the fund. A motion was also made and carried that the *Journal of the American Medical Association* keep a standing appeal in its columns for subscriptions to the Rush Monument Fund.

The report of the treasurer, Dr. H. P. Newman, showed that there was a balance on hand, January 1, 1897, of $9075.94; receipts for the year ending December 31, 1896, $44,141.14; expenses for the same period, $41,811.14.

A resolution was offered by the Executive Committee, and carried, that there be made an Executive Council of five, consisting of three officers of the Executive Committee and two officers to be chosen by election. Of this council of five, one must belong to the Section on Practice of Medicine and one to the Section on Surgery and Anatomy. The duties of the Council will consist in the transaction of the duties commonly delegated to the Executive Committee during the intervals between the meetings.

SECTION ON PRACTICE OF MEDICINE.

FIRST DAY—JUNE 1ST.

ON calling the section to order the Chairman, DR. J. H. MUSSER of Philadelphia, spoke of the inspiration that all must feel in meeting in this early home of American medicine. He felt that the time of the section would be best improved by taking up the scientific work instead of indulging in compliment and greeting.

DR. W. B. CAMAC of Baltimore, read a paper, entitled

THE SCHOTT TREATMENT OF CARDIAC DISEASE.

No satisfactory theory has ever been advanced to explain fully how this treatment meets the indications and produces the results which are claimed for it. Schott himself explained it on the theory of the reflex action of the nerve-centers. Lauder Brunton and Ludwig have discovered that the muscular system has a capacity of storing blood equivalent to that of the internal organs and the skin, and explained the actions of the Schott treatment on the theory that the resistant treatment and the baths combined stimulate the muscular system to such a degree as to relieve resistance in the peripheral circulation, but, whatever the theory of its action, the results obtained by the treatment at Neuheim are undoubted in reducing the size of enlarged and dilated hearts. This method of treatment has been introduced into the Johns Hopkins Hospital for the purpose of testing its efficacy not only in cases of heart disease but in affections of the kidneys. The report embraced the results of ten cases; of these four patients had died, two were not improved, one showed improvement only while under constant treatment, and in three the permanent results were most satisfactory. Some of these were cases of chronic nephritis in various stages of advancement, but all of the patients had enlarged or dilated hearts. In connection with the Schott treatment, however, various heart stimulants, such as nitroglycerin, digitalis, strophanthus, and strychnin were used as indications demanded. The conclusions of the experiments were that, while extensive changes in the position of the cardiac beat were obtained in all, that effect alone does not imply permanent improvement. In Bright's disease it cannot be depended upon for any satisfactory results.

DR. OSLER of Baltimore, in discussing the paper, said that in suitable cases the Schott treatment is undoubtedly of positive advantage. The objection to it is that it is difficult to carry out, the class of cases in which it is indicated are those of moderate dilatation of the heart without much degeneration of its muscular substance. This condition is usually found in heavy drinkers, between the ages of forty and forty-five.

DR. STOCKTON of Buffalo believes that the Schott treatment is dangerous when applied indiscriminately to cases of heart disease, and insisted that it should be carried out with great caution. In the baths at Neuheim, the water is charged naturally with gas. In imitation of this he had in some cases used ordinary cylinders of carbonic gas, allowing it to escape through a tube into the bottom of the bath. Dr. Woods Hutchinson had suggested to him an explanation of the beneficial effect of the gas by saying that it afforded a certain propulsive force to the blood-vessels and so relieved the heart by assisting the circulation.

DR. J. H. HERRICK of Cleveland said that as far as he had been able to investigate the subject, the treatment had no definite reference to the etiology of the disease. In all treatment some relationship to the etiology of the difficulty as well as the organic disease was demanded. For himself, he found more satisfactory results in proper attention to the eliminative and excretory functions and in proper nutrition.

DR. MORRIS of New York, in opposition to what Dr. Herrick had just said, insisted that the subject as presented in the paper was pertinent and practical. He had found enlargement and dilatation of the heart common, especially among beer-drinkers. He commended the Schott system of exercise in gastralgia. In his hands it had produced marked effect in diminishing the area of dulness of the heart in such cases.

DR. CAMAC, in closing the discussion, said that the effect on the kidneys is greater when the salt bath is given than when plain water is used, either hot or cold. In his paper he had given almost exclusive attention to the baths, but in connection with them, the prescribed gymnastic drills, such as were used at Neuheim, had been employed. For this purpose some of the nurses at the Johns Hopkins Hospital had been trained to apply the resistance exercise treatment. The food and diet had also been carefully regulated. In none of the cases had mountain climbing been tried, although this was a part of the systematic Schott method.

DR. D. L. ROCHESTER of Buffalo presented a paper upon

THE PROGNOSIS AND THERAPEUTIC INDICATIONS IN HEART DISEASE.

He classified all heart diseases into (1) disease of the cardiac valves; (2) disease of the blood-vessels; and (3) disease of the heart muscle. It had been his experience to have patients brought to him in conditions regarded as utterly hopeless, and, by proper treatment, he had been able not only to relieve them temporarily but to give them years of comfortable existence. Even in the most serious conditions of heart disease, it is never prudent to give an unfavorable prognosis until trial has been made by proper treatment to improve the tone and strength of the heart muscle and the arterial walls. His treatment consists in absolute rest in bed, the free use of cathartics, diuretics, diaphoretics, baths, passive exercise, and a liquid diet. Proper nutrition and exercise are important factors in the later management of the cases.

DR. J. B. HERRICK of Chicago strongly advocated the revival of venesection as a therapeutic measure of inestimable value. It is of especial service in cases of general edema and cyanosis. He narrated three cases of myocarditis in which he had applied this treatment with saving effect. In each instance he had drawn from sixteen to eighteen ounces of blood; in all of them the improvement was prompt, and in two of them it had been permanent.

DR. MARVIN of Louisville, Ky., strongly advocated the use of strychnin hypodermically in cases of acute dilatation of the heart. His method is to begin with one-twentieth of a grain of the drug and to increase it steadily until he obtains the physiologic effects. Rest in bed and carefully regulated nutrition are also potent factors in reaching permanent results.

DR. J. M. UPSHUR of Richmond, Va., endorsed what the previous speaker had said with regard to strychnin, and advocated the use of nitroglycerin alternately with the strychnin.

DR. WAINWRIGHT advocated venesection in extreme conditions due to heart disease. He reported the case of a woman suddenly presented to him in extreme cyanosis from senile heart disease, from whom he removed eighteen ounces of blood, with prompt and lasting benefit.

DR. ROCHESTER, in closing the discussion, said he used tincture of nux vomica as a heart tonic. He gave it in large doses, gradually increasing up to 1 dram three times a day.

DR. C. F. HOOVER of Cleveland read, by invitation, a paper, entitled

REDUPLICATION OF HEART SOUNDS.

Various theories have been advanced to account for the phenomenon of double sounds of the heart. He discussed these very elaborately and reached the conclusion that negative tension in the thorax, not compensated for by increased strength of the heart beat, occasioned an asynchonous action of the two sides of the heart. This necessarily produced the double sound.

DR. HENRY BEATTES of Philadelphia read a paper upon

THE USE OF DIGITALIN WITH REFERENCE TO THE DOSE.

Digitalis has long had the reputation of being a most uncertain drug. It has been discovered that the contradictory physiologic effects are due to the existence of elements in the crude drug having diametrically opposite properties. The attention of the pharmacist has therefore been directed to separating and refining the different alkaloidal elements. There are now upon the market two preparations of digitalin, one known as the German, or Pure Merck, and the other as the French Merck, the former is readily soluble in water and alcohol, but not readily soluble in ether; the latter differs from this in not being readily soluble in water, and is also a more powerful drug and necessarily must be given in smaller doses. Digitalin, German, is the preparation he uses. One-tenth of a grain is the minimum dose for an adult, and one-half a grain the maximum dose. It does not produce irritation of the digestive track even when used for long periods of time, nor does it have any cumulative effect. It is indicated in all lesions of the heart except stenosis with dilatation. Cases presenting senile conditions were described in which remarkably favorable results were obtained.

DR. J. H. HERRICK, during the discussion of the paper, said that digitalis or digitalin acts upon the heart through the pneumogastric nerve. The one precaution which he wished to emphasize was that neither digitalis nor digitalin, either "French" or "German," should be given in inflammatory conditions of the heart. He was opposed to the routine treatment of heart lesions, no matmer what their nature, by any drug, and more especially by digitalis.

DR. HARRY TOULMIN of Philadelphia read a paper, entitled

TRACHEAL TUGGING.

He classified his cases into (1) very slight up-and-down movement, (2) slight up-and-down movement, (3) tugging, (4) extra tugging. Seventy-five patients were examined. Of these, 44 presented no symptoms which could be ascribed to this class, 19 belonged to class 1, 5 to class 2, 2 to class 3, and 5 to class 4. The phenomena of the moving of the trachea with the respirations or the pulsations of the heart were due, as a rule, to aneurism of the ascending aorta.

DR. HELEN BALDWIN of New York read a paper upon

THROMBOSIS OF THE BLOOD-VESSELS OF THE NECK.

She reported the case of a colored girl, aged twenty, who presented the symptoms of pain in the left side of the neck and in the axilla. There was extreme dilatation of the heart and panting respiration. Temperature taken in the mouth varied between 94° and 96.5° F., while in the rectum it was constant at 102°. The external jugular was plainly defined and had the feeling of a hard cord. The patient developed signs of pneumonia, and died on the tenth day. Autopsy revealed an enlarged heart, with organized thrombi in both the external and internal jugular veins. Many similar cases were cited from literature upon the subject, most of which terminated fatally in a short time.

SECTION ON SURGERY AND ANATOMY.

FIRST DAY—JUNE 1ST.

THE section was called to order by the Chairman, **DR. REGINALD H. SAYRE** of New York, who made a brief address contrasting the surgeons of the past with those of the present and alluding to the steady development of the science.

DR. B. MERRILL RICKETTS of Cincinnati read a paper, with the title

LIGATION OF THE COMMON CAROTID FOR TRIFACIAL NEURALGIA, WITH EXPERIMENTS AND OBSERVATIONS ON DOGS.

The paper was illustrated by specimens and charts of the arterial and nervous systems. The pain in neuralgia, the speaker said, is due to anemia or congestion. In early life congestion is the common cause, while in advanced years anemia is the usual factor. The effect of ligation of the common carotid artery is to diminish the blood pressure. In experiments on dogs he had found that no histologic change occurs in the nervous structure after the ligation. He reported the case of a man ninety-six years of age, who suffered from trifacial neuralgia and who was very much benefited by the ligation of the carotid artery. The profuse hemorrhage accompanying the operations of Rose, Hartley, and Kraske were contrasted with the bloodless operation of ligation of the carotid.

DR. J. MCFADDEN GASTON of Atlanta read a paper, entitled

THE NERVE ELEMENT IN SURGICAL PATHOLOGY.

He said it was a fair inference that relief from pain may also indicate a curative influence. Success in surgical operations depends not a little upon the frame of mind of the patient and the nature of the surroundings. The speaker believed shock to be due to the continuous baleful influence induced by the injured tissues, which influence may be arrested by removing the part. The importance of recognizing the neuropathic diathesis cannot be overestimated. There are many evidences of the effects of nerve reflexes which could be alluded to. The writer presented the following conclusions:

1. The cutaneous development of the minute branches of the cerebrospinal system of nerves and the ganglionic ramifications of the great sympathetic are so related to the capillaries as to establish a reciprocal action between them and the great nerve-centers.

2. The vasomotor nerves are so intimately linked to the excitomotor, the excitosecretory, and excitodynamic system of nerves that the impressions made through the superficial afferent nerves are conveyed to all the corporeal structures and tissues so as to produce their effects on the different organs.

3. Reflex phenomena depend upon a complex interchange of local pathologic conditions with the nervous ramifications to remote parts of the body.

4. The fountain head of energy for all functions lies in the nerve-centers, and by controlling emanations from this source of power, the vital forces will be propagated with regularity and uniformity to all the remote parts of the physical organism. On the contrary, a hurtful influence disseminated from the nerve-centers causes disease of different organs.

5. The means to be adopted for avoiding injurious impressions upon the nerve-centers and the measures to be used for the correction of their derangements, make up the whole prophylactic agency of hygiene, and include all the therapeutic appliances in the treatment of the disease as well as the application of surgical measures.

6. Close observation of the various modifications of the nerve element in the physical organism should reveal its direct influence in surgical pathology and lead the surgeon to the adoption of proper means of relief.

DR. J. EWING MEARS presented a paper upon

OPERATIVE PROCEDURE FOR THE RELIEF OF OCCLUSION OF THE JAWS.

Closure of the jaws may be due to sloughing, ulcerating, cicatricial contraction, or to spasm. The spasmodic variety may be brought about by irritation of the fifth nerve, delayed or difficult eruption of the three lower molar teeth, etc. In the case of closure of the jaw from difficult eruption, the mouth should be forced open and the second molar extracted, or the third may be removed if displaced or otherwise abnormal. In all cases of spasmodic closure the cause should be removed.

The chronic or permanent form of closure of the jaws results also from rheumatic and other diseases of the articulation with the deposit of bone in the joint. Perhaps the most frequent cause of this class of cases is fracture of the condyle which has been recognized. The cause of occlusion of the jaws may be unilateral or bilateral. In each case a careful examination should be made in order to determine the best method of procedure.

The following conclusions were drawn:

1. Jaw closure due to the presence of cicatricial tissue in the buccal spaces can be most efficiently relieved by the formation of a canal lined by normal membrane by means of a ligature passed behind the cicatricial mass, reunion of the divided tissues and reformation of the nodular tissue not occurring after division when this canal has been formed.

2. Ankylosis of the temporomaxillary articulation producing jaw closure can be best relieved by removal of both coronoid and condyloid processes with the upper portion of the ramus, thus affording ample space for the formation of a freely movable false joint. The operation should be performed through the mouth, thus avoiding disfiguring cicatrices.

DR. ERNEST LAPLACE of Philadelphia read a paper upon

IMPROVEMENT OF BRAIN FUNCTION BY SURGICAL INTERFERENCE.

The two great symptoms of brain troubles which call for interference are pain and disturbed function. In operating, the two dangers to be guarded against are shock and sepsis; the former is to be avoided by careful hemostasis, by the use of strychnin and external heat, and keeping the head low, the latter by the strictest antiseptic precautions. In congestion and other conditions in which general swelling was supposed to be present, the author has performed transverse linear craniectomy. After removing a portion of bone he incises the dura throughout the whole length, avoiding the superior longitudinal sinus. The wound is packed with sterile gauze, the ends of which come out at either extremity, the scalp then being united. On the eighth day the sutures and gauze are removed. He also referred to trephining for epilepsy, and linear craniectomy for microcephalus, in both of which conditions he had obtained favorable results.

DR. M. H. CRYER of Philadelphia demonstrated on the cadaver a new surgical engine, which is a modification of the well-known dental engine, more powerfully made and constructed to run at a greater speed. The advantages claimed for this engine are the ease and accuracy with which any portion of bone can be removed and the compact and aseptic construction of the apparatus.

The last two papers were discussed together. DR. WYMAN of Detroit coincided with the views expressed by Dr. Laplace. DR. J. WILLIAM WHITE thought the possibilities of evil which would follow the general adoption of the radical measures advised by Dr. Laplace should not be overlooked. Taking into consideration all brain operations by surgeons the country over, the mortality would be considerably more than that expressed in the paper referred to. It is necessary to distinguish between infected brain lesions which require drainage and other conditions in which this could not possibly result in any benefit, such as cases of arrested development, insanity, and others of this class. A diffuse brain lesion cannot be drained through one opening, or even through a series of openings. A very large number of cases must be observed before it is safe to say that improvement is to be expected after these procedures. The immediate result of the operation itself should be taken into account. In a paper published a few years since on "The Effect of Operations, *per se*," he had showed that improvement in a large number of conditions had followed simple explorations or other measures that could not possibly have affected the condition. We cannot, however, from these cases base conclusions which would warrant us in advising these operations upon other patients. In cases of localizing symptoms, either of abscess, tumor, or depressed fracture, the indication for operation is distinct and imperative, but without some clear-cut symptom of abnormal intracranial condition, which could probably be remedied by trephining, he would hesitate to advise operation.

DR. FRANK STAHL of Chicago read a paper, entitled

ONE OF THE RARER FORMS OF HERNIA.

He included two forms—one partial intestinal-wall hernia, and diverticula hernia. The former is generally acceded to occur in a chronic condition, but many eminent authorities deny the existence of the acute condition of partial herniæ. He described the mechanism of the occurrence of this condition, and referred to cases in which it had been present beyond doubt.

SECTION ON OBSTETRICS AND GYNECOLOGY.

FIRST DAY—JUNE 1ST.

The Section was called to order by the Chairman, DR. MILO B. WARD of Topeka, Kan.

In the absence of the Secretary, DR. H. M. FISHER of Philadelphia was elected to fill the position.

DR. WARD, in his address, presented a review of some of the work accomplished in gynecology during the last half century, dwelling particularly upon the labors of honored members of the American Medical Association. Sims and Emmet, he said, were the pioneers of gynecology in America, and they were ably seconded by such eminent followers as Peaslee, Thomas, Goodell, Fordyce Barker, Parvin, and a score of others. Numerous innovations and valuable suggestions in the treatment of the various gynecologic conditions came from them. He called attention to the fact that to this great medical organization must be accorded credit for the movement that resulted in the separation of gynecology from obstetrics, and the establishment of special chairs of gynecology in the various medical colleges of the land. The question of the advisability of the removal of the uterus in suppurative disease of the adnexa has agitated the minds of gynecologists during the past year, and the tendency toward this radical procedure has largely developed, although there are many and able men opposed thereto.

No universal rule has been as yet found for the operative treatment of uterine fibroids. The prevention of vaginal prolapse after total extirpation of the uterus is a puzzling question. The method of anchoring the vaginal walls to the broad ligament pedicles is probably the best that has as yet been suggested. Carcinoma of the cervix is an indication now for the entire removal of the uterus in preference to amputation by the knife or by the galvanocautery, although some operators still adhere to these methods, especially in the so-called inoperable cases. Hysteropexy and Alexander's operation have been thoroughly discussed during the past year, and many interesting reports and arguments for and against these procedures have been presented.

A CONSIDERATION OF SOME OF THE CONDITIONS INFLUENCING THE RESULTS OF THE SURGICAL TREATMENT OF UTERINE RETROPOSITION

was the title of a paper presented by **Dr. Augustus P. Clarke** of Cambridge, Mass. He stated that retroversion of the uterus is generally preceded by a certain amount of prolapse, due to a yielding of the supports from below. Usually the axis of the cervix is nearly at right angles to the axis of the vagina. Any deviation from this position is not to be considered as pathologic until the axes of the two organs nearly correspond. In some instances fatty degeneration of the round ligaments causes them to become unable to support the uterus, and adhesions also help to drag this organ out of place. In order to restore the uterus, these adhesions must be separated and the round ligaments shortened. The genupectoral position, with gentle manipulation, will best restore the uterus to its normal position when it is found to be resting between the uterosacral ligaments. The danger of hernia following the operation of shortening the round ligaments has been advanced as an objection to the performance of this operation, but proper precautions will suffice to prevent this complication. Ventrofixation or ventrosuspension has become a favorite operation for the cure of the lesion. This operation in certain cases sets up a most distressing pathologic condition, and should not be performed in women who have not yet reached the menopause. The chief cause of the failure in operations for retrodisplacement is the persistence of adhesions. In such cases hysterectomy is the best method for insuring permanent relief.

In the discussion which followed, **Dr. Werner** of Philadelphia said that she wished to place on record the cases of two patients who had suffered from the condition described in the paper. By the use of rest, packing, and a year's persistent treatment, cure resulted, and in one instance the patient passed successfully through two subsequent pregnancies. There was, however, still some tendency to prolapse. The second case was similar. She wished especially to ask the author of the paper what result was to be expected in subsequent pregnancies after the various operative procedures, and whether stretching would recur?

Dr. M. Price of Philadelphia said that in thirty-years' practice he had not seen one case of retrodisplacement that could not be cured. Purely medical means will answer in the case of patients that have not been torn in labor. He objects to shortening the round ligaments, and believes that Nature never meant these ligaments to support a hair's weight. The diseased condition consists essentially of an atrophy of the uterine wall, and it should be treated by some mechanical support in the uterus itself or by some support from below. Ventrofixation or other operations of the kind are mischievous. The pedicles, after the serra-neude method of hysterectomy, will ultimately stretch, and if this is true, to how great an extent will the uterus be held up by the tiny round ligaments?

Dr. Sell of New York believes in medical gynecology. Massage, internal and external, will break up the adhesions and restore the normal condition. Gymnastics should also be tried, the patient lying flat upon the floor and moving her limbs in such a manner as to produce constant tension of the uterus upward. This maneuver should be repeated two or three times weekly, the interval gradually being increased.

Dr. Joseph Eastman of Indianapolis remarked that before considering therapeusis we should always consider condition. Uterine displacement and chronic constipation are the two great causes of the diseases of women. Exhaustion of the life of the pelvic plexus of nerves, the result of over-sexual indulgence, is the cause of many cases of chronic constipation. The uterus, to a certain extent, is an erectile organ, and in these cases it needs physiologic rest, and if any mechanical support is required, he would suggest a "barbed-wire" pessary.

Dr. Rosenthal of Indiana stated that no condition gives the gynecologist such trouble as retrodisplacement of the uterus. It is a condition found in the young girl as well as in the married woman. It is especially apt to occur in women in whom the bladder is attached to the uterus low down, so that the cervix is drawn forward, that is, where there exists a shortening of the anterior vaginal wall. He believes that the pessary is useful in its place, especially in cases originating *post-partum* or *post-abortum*.

Dr. Joseph Price of Philadelphia stated that, in all his practice, he had not seen a woman who could not nurse her baby, and yet it is becoming common, he understands, for women to refuse to do so, and for this reason subinvolution is becoming more frequent. The older gynecologists met with success merely from the use of pessaries in these displacements. The doctor of to-day prefers to put his patient to bed for three or four weeks, and do a ventrofixation, while refusing to give three or four-weeks' time in bed with the use of the pessary. He is opposed to both Alexander's operation and ventrofixation. He has undone many ventrofixations. The pessary is all that is needed if the floor of the pelvis is restored.

Dr. Goldsphoon of Chicago regretted the difference of opinion advanced by the various speakers. He believes that the round ligaments hold the fundus uteri forward, and that the uterosacral ligaments draw the cervical zone backward, producing normally an anteversion of the organ. If either of these ligaments stretches, the organ falls back. If this retroversion is due to a stretching of the uterosacral ligaments, Alexander's operation will not cure the condition, while if the round ligaments are at fault, this operation is the best procedure with which we are acquainted.

DR. H. M. FISHER of Philadelphia said that the uterus has no fixed normal position. It can readily be retro- or lateroverted, and varies in position with the degree of fulness of the bladder and rectum. It is, in other words, in a state of mobile equilibrium. Upon the cause of the retrodisplacement will depend the method of treatment. We may have a puerile retrodisplacement due to chronic constipation. The most frequent cause, however, is to be found in the puerperium as the result of a tight bandage, dorsal decubitus, and chronic constipation. Involution is thus prevented, and a permanent retrodisplacement follows. It is not every retrodisplacement of the uterus that gives rise to symptoms.

DR. HALL of Missouri thought that the results of Alexander's operation are worse than the disease. Too many herniæ have followed the operation, especially in fat women. He believes that the future operation is not Alexander's procedure, but fixation of the uterus through the vagina, according to Vineburg's method.

DR. HUMISTON of Cleveland saw Alexander's operation performed by Alexander himself ten years ago, and was favorably impressed. But he has seen so many failures following it that now he finds no indications for its performance. If the adnexa are diseased, the only thing to do is to remove them by abdominal section, and then replace the uterus; if they are not diseased, we can succeed by the conservative method of treatment.

DR. MASSEY of Philadelphia believes that the inflammatory condition always precedes the displacement, and not the displacement the inflammation.

DR. LAWRENCE of Columbus said that the symptoms from which the patients suffer are not directly dependent upon the displacement, but upon the metritis, endometritis, peritonitis, adhesions, and diseased adnexa that accompany it. Shortening the round ligament in this condition is not devoid of danger. The anteflexion resulting from ventrofixation is just as serious a matter as the retrodisplacement, and the patients cannot be very much benefited thereby. Shortening the round ligament by an abdominal section will accomplish the work without any serious condition following.

DR. JOSEPH PRICE read a paper on

MECHANISM AND TREATMENT OF PERINEAL LACERATIONS. (See page 734.)

DR. STONE of Washington considers Emmet's operation the most difficult of all operations in surgery. Tait's operation, he thinks, is of service only in restoring torn tissues, and not the floor above. Emmet never ties his sutures until all are applied, including the crown suture. The latter is applied from the myrtiform caruncle upward and inward, including the crest of the rectocele, and out at the corresponding point in the other side, thus, when tied, shortening the vagina.

DR. M. PRICE said that, in denuding the muscle in complete tears, it is necessary to bury a tenaculum deeply into the dimple so as to catch the muscle to be repaired. The first set of sutures in the vagina is closed. The second set of sutures is passed from the perineum toward the vagina, the last two sutures of this set being known as the sphincter sutures. The retracted edges of the muscle are drawn up and the needle plunged through. The union should be only moderately tight so as to avoid cutting. Failure will then not occur.

DR. EASTMAN said that, in restoring the floor, he dilates first the sphincter and then secures relaxation, so that the anus does not so nearly approximate the vulvar orifice, and thereby gets more space in which to form the floor. This dilation should be done by an assistant or nurse who does not aid in the subsequent operation.

SECTION ON DISEASES OF CHILDREN.

FIRST DAY—JUNE 1ST.

The address of the Chairman, DR. J. A. LARRABEE of Louisville, Ky., was in the nature of a history of the Section.

A letter was read from DR. A. JACOBI, the organizer of the Section, and its first President, who stated that it was not founded but was in the air—a "spontaneous generation." It was the sixth section formed in the history of the Association. Mention was made of the rapid strides in pediatrics, its establishment as a specialty, and its separation from the Chair of Obstetrics in our medical colleges. Scarcity of pediatric literature was until lately to be deplored, but this can be no longer urged. A suggestion was made that a censorship be created over medical literature because of the large number of papers now unnecessarily presented.

DR. O. W. BRAYMER of Camden, N. J., read a paper, entitled

THE ANTISEPTIC VERSUS THE ANTITOXIC TREATMENT OF DIPHTHERIA.

The author's opinion was that antitoxin does not deserve the reputation it has acquired. He advocated local antiseptic treatment, and quoted statistics of cases occurring in his practice in which chlorate of potash and iron had alone been used with most gratifying results.

THE TREATMENT OF DIPHTHERIA

was the title of a paper read by DR. JOHN H. COUGHLIN of New York. He said, in part, that a better understanding of the action of old remedies is more to be desired than constant experimentation with new ones. In the treatment of diphtheria it is very essential to keep up the nutrition. Nourishment should be given in small quantities, and often. Large quantities of alcohol should never be given to children, for, aside from the catarrhal condition of the gastro-intestinal tract that ensues from such ingestion, the eliminative organs become overworked.

THE SERUM-THERAPY OF DIPHTHERIA

by DR. EDWIN KLEBS of Chicago, was the title of a paper read by the author's son. The writer had arrived at the conclusion that both antitoxic and bactericidal properties were inherent in the serum, and that both worked to produce a cure; they are not products formed in immunized animals, but are transformed from injected culture fluid.

Dr. Edwin Rosenthal then read a paper on

THE SPECIFIC USE OF DIPHTHERIA ANTITOXIN IN LARYNGEAL DIPHTHERIA,

and was followed by **Dr. W. W. Gray**, of Bridgeport, Conn., who presented one with the title,

THERAPEUTICS OF DIPHTHERIA WITH SPECIAL REFERENCE TO ANTITOXIN.

During the general discussion of these papers **Dr. Frederick A. Packard** of Philadelphia said that the statistics that had been quoted in favor of the antitoxin treatment of diphtheria were most convincing. He doubted the value of the agent, however, as a prophylactic, as in a number of instances in which he had made use of it for this purpose it had proved ineffectual.

Dr. W. P. Northrup of New York said that every member of the staff of the Willard Parker Hospital for Contagious Diseases, New York, with one exception, heartily endorsed the use of antitoxin. As far as its prophylactic value is concerned, the record made at the New York Infant Asylum, when a serious epidemic was stopped by the injection of small immunizing doses, is convincing. During the pre-antitoxin days the speaker had had twenty-two successive deaths after intubation in private practice, and Dr. O'Dwyer had had twenty-five in spite of the best treatment then known.

SECTION ON MATERIA MEDICA, PHARMACY, AND THERAPEUTICS.

FIRST DAY—JUNE 1ST.

Chairman, **Dr. Warren B. Hill** of Milwaukee.

The Section was called to order at three o'clock. The chairman made a brief address of welcome to the members of the delegation from the American Pharmaceutical Association, which was responded to by Dr. F. E. Stewart, chairman of the delegation. The secretary read a communication from the Philadelphia College of Pharmacy, extending an invitation for the Section to hold its sessions in the lecture-hall and museum of the college. On motion, it was resolved to visit the College of Pharmacy on June 4th, and to hold the Thursday afternoon session there.

The first paper, entitled

CELANDIN; ITS PHARMACOLOGY, PHYSIOLOGIC ACTION, AND THERAPY,

was read by **Dr. John V. Shoemaker** of Philadelphia.

The extravagant claims made about a year ago in favor of celandin (*Chelidonium majus*) led the reporter to investigate the subject clinically in the treatment of cancer of the skin and in cases of psoriasis and similar conditions, for which the drug had been recommended by a Russian physician. Dr. Shoemaker's results were disappointing. He could not obtain the effects which had been reported, and considered that the claims were not well-founded. He used a fluid extract made with equal parts of glycerin and water as a medium, as recommended in the Russian papers, internally and locally, topically and hypodermically. While the drug has no special action in cancer, it is a good tonic in moderate doses, a stimulant in larger ones, and a purgative if large doses are given. By its physiologic action upon the bronchial mucous membrane, it is expectorant, and generally is a stimulant to the glands of the skin and mucous membranes. It is efficacious in the treatment of cases attended by infiltration of the skin, as in chronic local eczema and psoriasis, but has no power to influence or retard the progress of cancer.

Dr. F. E. Stewart said that there had been many cancer specifics brought forward and they had all followed the same course. He recalled the history of the introduction of another drug some time ago, when the newspaper accounts of its wonderful effects in Europe had caused such a demand for it, that an amount of syrup and extract representing more than two tons of the remedy was sold in the United States before an ounce of it had been imported. This shows the unreliability of the preparations that are sold to the public. He asked if the reader of the paper had noticed any difference between the effects of the recent herb and the dried specimen.

Dr. Thornton said that the claims of the Russian physicians for celandin were also made by Dr. Spivak, now of Denver, who published a clinical report of successful cases. The report was valueless, however, because it was not accompanied by data of microscopic examinations of the tumors. He congratulated Dr. Shoemaker upon reporting his negative evidence, which is of great assistance, especially to the younger members of the profession.

Dr. Shoemaker said that he had come to the conclusion that the great multitude of new drugs that are thrust upon the medical profession put us in a very awkward light before the public, especially those which are known by newly coined words and expressions. There is one consideration in favor of celandin and that is, that it is official. When, a number of years ago, he wrote his book on "Therapeutics" he tried to include all the new remedies, and had since found many of them to be worthless. In reply to Dr. Stewart, he stated that he had used both the fresh and the dried drug with all the precautions recommended by the Russian reporter and had found them equally worthless in the treatment of cancer.

Dr. C. C. Fite of New York read a paper, entitled

A PLEA FOR UNIFORMITY IN DIASTASE TESTS.

Dr. F. E. Stewart of Detroit said that as the paper brought up a question of much importance and was the result of an extended investigation, he moved that a committee be appointed, consisting of the Chairman of the Section and two other members, to suggest a practical test for diastase and to recommend the same to the Committee on Revision of the United States Pharmacopeia, and that the result of their deliberations be transmitted to the American Pharmaceutical Association for its concurrence. He said that he had himself given considerable attention to the subject, and as a result of about three thousand tests made under his direction by competent chemists, he had found a great variety of methods in use and corresponding differences in the results. Active diastase has great starch-transforming power; for instance, a few grains are sufficient to convert all the starch taken in during an ordinary meal by an adult man in the period of less than a minute of time. Many of the preparations said to contain diastase have no starch-digesting power whatever. Everything depends, therefore, on the quality of the diastase, and some regulation is urgently needed so as to enable the physician to differentiate between the true diastase preparations and those which are falsely alleged to contain diastase.

DR. F. R. STODDARD of Shelburne, Vt., said that he had been impressed with the importance of the positive determination of the digestive power of diastase, and preparations which claim to have diastatic power, and of the necessity of the establishment of some uniform test by authority of the Pharmacopeia. This is a question which should interest every physician who prescribes these remedies. The manufacturer under present conditions sends out these preparations, and the physician uses them expecting them to fulfil the claims of the manufacturer, and that they will do a certain amount of work in the digestion of starchy foods, but at present he has no means of knowing whether these claims are true or false.

The Chairman said that the question was of great importance, because the American people are very prone to suffer from what may be called amylolitic indigestion, owing to a number of contributing causes. In the first place there is too much starch in our food, and in the second, owing to hasty deglutition, there is a deficiency of ptyalin. There is therefore a great demand for diastase and preparations which claim to assist in the digestion of starchy foods, and there is no doubt that some form of diastase will be introduced into the next Pharmacopeia. A proper test should therefore be established and a standard be made before its introduction.

DR. F. WOODBURY of Philadelphia said that the chemistry of the digestive processes is now so well understood by physicians that the form of dyspepsia characterized by deficient amylolitic power in the secretions is generally recognized. As a result, physicians no longer prescribe pepsin for all conditions of imperfect digestion, but they differentiate the cases in which a starch-transforming ferment will afford the desired relief from those in which the proteid digestion is at fault. Therefore, measures to promote the secretion of saliva and of the pancreatic and intestinal juices, are recommended, and there is a constantly increasing demand for starch-transforming ferments by the profession. It is most important, therefore, that some uniform test should be formulated by the biologic chemists, which may enable us to distinguish between the physiologically active and the inert or fraudulent diastatic preparations offered to us by the manufacturers.

Dr. Fite, in reply to a question, said that he had stated that the acidity of the gastric juice will retard the action of diastase in the stomach. In cases of hyperacidity it is necessary to administer an alkali before the meal, and then by the use of diastase taken with the food the difficulty can be overcome and the symptoms relieved. The reason why so many physicians have failed to relieve patients suffering from starchy indigestion is because the existence of this condition of hyperacidity, and neglect to administer the alkali before meals. Bicarbonate of soda in 10 to 20-grain doses immediately before each meal will be of great assistance to the action of the diastase taken during the meal. Six years ago, when he first took up the study of this subject, diastase was practically unknown to a majority of practitioners, whereas now it is used to a great extent by physicians all over the world. The loss of saliva by tobacco-chewers, the defective mastication of food, and the limited secretion in young children, with the great proportion of starch in our food as pointed out, all contribute to make diastase and its preparations prominent in therapeutics, and there should be some method of standardizing these products, or of ascertaining the real value of diastase by some practical and convenient test.

The Chairman put the motion; which was adopted unanimously, and he appointed Drs. Fite and Stewart to serve on the committee with himself.

The Chairman then delivered his Address, in which he referred to the valuable contributions rendered by pharmacy and analytical chemistry to the science of therapeutics. He deprecated the use of ready prepared formulæ, and secret or proprietary preparations by the profession, and urged upon physicians a closer study of the resources of the Pharmacopeia. The brilliant results from the introduction of the serum-therapy are now attracting general attention to this new method of treatment, and encourage the hope of greater success in future in controlling infectious disease. The use of toxins, for the purposes of immunization, which has been so successful in the biologic laboratory, leads to the belief that this method, though still in its infancy, promises much. He believed that it might be possible to extract the active principle from this class of agents in the same way that quinin is extracted from cinchona, and that in the future these chemical substances, thus obtained, will occupy an important place in therapeutics.

DR. F. WOODBURY said that the use of ready-made preparations by the profession is largely the result of routine practice. Each patient should have his case especially investigated by the physician so as to ascertain the presence of any latent disease, such as nephritis, diabetes, or tuberculosis, for instance, and the tendency to prescribe for symptoms should be discouraged. The serum treatment is still in the empiric stage and cannot be considered well established upon a scientific basis until, as Dr. Hill had suggested, the active principles have been isolated and properly investigated.

DR. STEWART moved that the address be sent to the Executive Committee with a request to report its action thereon to the general session. This motion was adopted.

DR. HILL said that, in regard to immunization by toxins, he would mention a case in illustration. About two years ago, he accidentally immunized a man from erysipelas by injections of serum from the streptococcus erysipelatus. The man had an inoperable sarcoma, and he had tried Dr. Coley's toxins for the purpose of experiment and of amusing the patient rather than from any hope of a good result. At first he used from five to ten minims (.01–.015 cc.), which afforded a decided reaction, but finally no reaction occurred after an injection of ten centimeters of toxin. He was absolutely immune. It is generally said that this protection is due to some change in the leucocytes and their secretion, but it is due, in the speaker's opinion, to some modification in the fixed cells of the tissues. There were two sets of results from the above experiment: (1) When a patient is liable to be infected from the streptococcus in a wound, not due to unclean surgery, but in the necessarily suppurating cases, if we know this in advance of operation, we may render the patient immune in this way. (2) The action of the antitoxin in the system is also to be considered. This is a broad field for investigation by organic chemists. Patients become protected against morphin so that large doses have no toxic effects. It has been shown that the blood taken from a rabbit which has been rendered immune from large doses of morphin will render another rabbit, after injection into its blood-vessels, also immune against the drug. This acquired immunity from poisons is accompanied by certain changes in the blood and fixed tissue cells and if, as we know, man can be protected from vegetable and metallic poisons by a course of treatment, he may similarly be protected from various diseases in which toxins are produced. After the reapers in the field of bacteriology have done their work, it will be our duty to take it up where they left off and perfect new therapeutic truths for application to diseased conditions.

SECTION ON NEUROLOGY AND MEDICAL JURISPRUDENCE.

FIRST DAY—JUNE 1ST.

DR. W. J. HERDMAN of Ann Arbor, Mich., Chairman.

DR. HERDMAN delivered the annual address, entitled

THE EVIDENCES OF THE PROGRESS OF NEUROLOGY AND MEDICAL JURISPRUDENCE.

He referred to the ready assimilation of new facts and discoveries in the histology of the central nervous system, and the rapid growth of literature in the form of text-books and monographs. It was most desirable that some effort at uniformity in neurologic terminology be made. The relationship of neurology to the humane sciences has proved stimulating and helpful. In medical jurisprudence the growing tendency to subordinate the *absolute rights* of individuals to fancied claims of society, is to be deprecated. In this connection a recent case in London was alluded to in which the surgeon had, contrary to the express and positive instructions of his patient, removed both ovaries on the plea that otherwise the patient's life would be shortened. Approval of legislation in the direction of unsexing criminals, epileptics, etc., was denounced as an unwarranted infringement of the absolute rights of man. The section should sanction by resolution the attempt at uniformity in neural terms, should relegate the work in medical jurisprudence to a separate section, and should endeavor to make this section the source of exact and authoritative information on the subject of neurology.

DR. CHARLES H. HUGHES of St. Louis read a paper, entitled

THE HISTORY OF AMERICAN NEUROLOGY,

in which he presented an exhaustive historical account of the achievements of American neurologists for upward of a century.

TRUNK ANESTHESIA IN LOCOMOTOR ATAXIA

was the title of an interesting paper by DR. CHARLES W. BURR of Philadelphia. This was discussed by Drs. Hugh T. Patrick of Chicago, C. C. Hersman of Pittsburg, and Moyer of Chicago.

THE PARALYSES, BY ONE OF THE MANY PARALYTICS,

by SAMUEL KNOX CRAWFORD of Chicago, Ill., was read by title.

DR. E. S. PETTYJOHN of Alma, Mich., presented a communication on

THE DIAGNOSIS AND TREATMENT OF INTERNAL CEREBRAL MENINGITIS CHRONICA.

He advocated galvanization of the brain as a valuable adjunct to the treatment of this condition, except in the acute febrile form.

The next paper, on the

DIFFERENTIAL DIAGNOSIS BETWEEN CEREBRAL SYPHILIS AND GENERAL PARESIS,

was by DR. HUGH T. PATRICK, and was discussed by Drs. Carpenter of Cleveland, Moyer and Jones of Minneapolis, and Hughes of St. Louis.

DR. AUGUSTUS A. ESHNER of Philadelphia read a paper on

HEREDITARY LATERAL SCLEROSIS,

in which he detailed cases of a mother and son similarly affected with this disease.

A paper, entitled

A CASE OF THOMSEN'S DISEASE COMPLICATED BY MULTIPLE NEURITIS,

by DR. M. NELSON VOLDENG of Des Moines, Iowa, and one on

PAIN TRAUMATISMS,

by DR. THOMAS H. MANLEY of New York, were read by title.

DR. W. S. WATSON of Fishkill-on-Hudson, N. Y., presented a paper on

MELANCHOLIA AND ITS TREATMENT.

He spoke of a case of myxedematous nature which was aided by the thyroid treatment. The paper was discussed by Drs. Canfield of Bristol, R. I., Hughes of St. Louis, Kindred of New York, and Spitzker of New York.

SECTION ON OPHTHALMOLOGY.

FIRST DAY--JUNE 1ST.

This section was called to order by the Chairman, DR. GEO. E. DE SCHWEINITZ of Philadelphia.

The first paper presented was by DR. HOWARD F. HANSELL of Philadelphia upon

ROENTGEN RAYS IN OPHTHALMIC SURGERY.

In this he described the ingenious methods and devices which had been invented in the application of skiagraphy to the eye. One of the first successful attempts had been made by putting the photographic film in the nostril and exposing the temporal side of the eyeball to the tube. Since this many successes had been attained by placing the plate or film in the canthus, or binding it upon the temples.

The subject was continued by DR. WM. F. SWEET of Philadelphia upon

LOCALIZATION OF FOREIGN BODIES WITHIN THE EYE BY MEANS OF X-RAYS.

Dr. Sweet explained how, by moving the tube a certain known distance, two shadows could be obtained upon the plate, and by a trangulation of the two shadows the exact location of the foreign body was determined.

Considerable discussion followed, in which it was stated that no accident or injurious effect had attended the application of skiagraphy to the eye, although in many instances the exposure had been prolonged.

GENERAL SESSION.

SECOND DAY—JUNE 2D.

The second general session of the Association was called to order promptly at ten o'clock by the President, DR. NICHOLAS SENN. Following the reading of the minutes of the preceding day's session, the Chairman of the Committee on Arrangements, DR. H. A. HARE, made announcements referring to the adjourned meeting of the American Medical Editors' Association, and to a communication received from the Atlantic City Medical Society, conveying an invitation to the Association, and to the American Academy of Medicine, to become their guests at Atlantic City on Saturday, June 5th.

THE ADDRESS ON MEDICINE

was then delivered by DR. AUSTIN FLINT of New York. (See page 732.)

On motion of DR. COTTER of New York the thanks of the Association were tendered to Dr. Flint for his able and interesting address.

During the interval preceding the arrival of President McKinley, a number of questions of general interest were considered and acted upon by the members. The secretary announced the *personnel* of the Committee on Nominations. This committee has charge of the naming of officers and of deciding the important point as to where the next annual meeting will be held.

The report of the Executive Committee was then read, and showed that at the present meeting 950 different members were in attendance at the various section meetings, the largest number ever recorded in the history of the Association. It was resolved that in future, in order to expedite the registration of members at coming conventions, the secretary of the Association be constituted a committee of one to conduct in the city where a meeting is to be held, for three days prior to the commencement of the meeting, a bureau of registration for the attending delegates, and that he receive the sum of one hundred dollars annually for such services.

The next question which engaged the attention of the delegates was the selection of the place of meeting for next year's convention, but no definite conclusions concerning this matter were reached, the subject finally being referred to an appropriate committee for decision. Delegates from Tampa, Fla., Milwaukee, Denver, and Columbus, proposed these cities as meeting places for the Association in 1898.

There were many violent expressions of disapproval, and a great many hot discussions anent the question of railroad rates to members of the Association, which next was taken up for consideration. The charges made by the trunk lines to medical men to and from the meetings of the Association were characterized as extortionate and unfair, and several delegates insisted that a formal protest be entered by the Association against this alleged discrimination, although in the end the consensus of opinion seemed to favor dropping this subject as one which the Association was helpless to remedy.

There now ensued a lengthy discussion relating to the duties of the Nominating Committee, but comment was finally stopped when it was shown that this committee must first report in due order, after which the body of delegates might or might not accept the report rendered them. It was further announced that the Nominating Committee would meet immediately after the adjournment of the morning's session, and again during the afternoon, to take up the business delegated to it.

The conclusion of these business matters had just been reached when the arrival of the President of the United States was announced. The Chief Executive advanced toward the front of the stage, leaning upon the arm of President Senn and escorted by Governor Hastings, Mayor Warwick, Dr. William Pepper, Dr. H. A. Hare, and a number of distinguished cabinet officers and diplomats, who had accompanied the President from Washington. After an enthusiastic reception by the audience, which rose to greet him, President McKinley made the following brief, but impressive, address:

"Although summoned to this city for another purpose, I deem myself most fortunate to find this honorable Association in its semicentennial meeting on the same day, and I could not refrain from taking a moment from the busy program mapped out for me by Dr. Pepper—whose assurance I had before coming here that it should be a day of rest, which I have already begun to realize—I could not refrain from pausing a moment that I might come to this brilliant presence, meet the learned body here assembled, and pay my homage to the noble profession you so worthily represent. You have my best wishes and, I am sure, the best wishes of all our countrymen for the highest results of your profession, and my warm and hearty congratulations on this the fiftieth anniversary of your society."

President McKinley was followed by Governor Hastings, who regretted his unavoidable absence of the preceding day, and expressed himself as highly honored by being invited to address such a distinguished gathering of scientific men, to whom he desired to extend the most cordial welcome of the Commonwealth. During the course of Mr. Hasting's address, he took occasion to say: 'As a layman, all I can do in regard to such a gathering as this is to stand on the sidewalk and watch the procession pass by. Hence, I can only give you the opinion we common, everyday people have of you, and the one opinion we hold to tightly. We laud you for the code of honor that exists in your profession—a code which many can afford to imitate. Your powers are great and untrammeled and your opportunities vast. The lawyer in the forum finds an opponent worthy of his steel; the judge on the bench is bounded by law and by precedent; the statesman is influenced one way and another by conflicting considerations; but the physician, in his court, is judge, jury, advocate, prosecuting attorney—sometimes executioner, and from his court there is no appeal. In the sick-room the doctor is an autocrat, and in that forum the American medical profession has determined that there shall be no room for quack or mountebank."

After the speech of the Governor, Dr. Horatio C. Wood of Philadelphia made a vigorous and well-timed speech, which embodied a resolution protesting against the passage by Congress of the bill now pending to regulate the practice of vivisection in the District of Columbia. Dr. Wood said that if the one hundred thousand physicians in the United States would take this as a personal matter, and act accordingly with their respective Congressmen, their influence in crushing the measure would be irresistible; and added, that every medical man should see to it at once that active measures are taken in regard to this question, which has for its purpose the governmental control of all experiments upon live animals, and renders, in certain instances, the practitioner of vivisection liable to prosecution for criminal misdemeanor. Dr. Wood also remarked that he believed that there must be a special chamber reserved in Hades for the American Medical Association, which has passed good resolution after good resolution concerning this question without effect—for the way to hell is paved with good resolutions. The enthusiasm aroused by Dr. Wood's speech, and the immediate adoption of the contained resolution lasted for several minutes, and, after its subsidence, the meeting adjourned for the day.

SECTION ON PRACTICE OF MEDICINE.

SECOND DAY—JUNE 2D.

The Section met at nine o'clock, with the President, Dr. J. H. Musser, in the Chair.

The first topic was the sero-diagnosis of typhoid fever. Dr. W. H. Welch of Baltimore opened the discussion with some remarks on the

PRINCIPLES UNDERLYING SERO-DIAGNOSIS.

He called attention to the importance of a proper diagnosis of typhoid fever in its early stages, especially in the South, where the prevalence of malarial and continued fevers made the clinical diagnosis difficult. The discovery of the typhoid bacillus was not immediately followed by the practical results in diagnosis and treatment consequent upon the discovery of the diphtheria and tubercle bacilli. Numerous attempts had been made to obtain cultures of the typhoid bacillus; first, by the juice of the spleen, withdrawn by a hypodermic needle, but the results were unsatisfactory, and moreover the danger of injury to the organ was considerable; cultures made from rose spots were tried, but proved unsatisfactory. The results obtained with cultures made from the blood were more apparent, but large quantities of blood, as much as ten cc., were required. With cultures obtained in this way good results had been obtained in twenty-seven per cent. of cases. The Elsner method of obtaining cultures from the stools marked an advance in the diagnosis of typhoid fever, but it was disappointing in that its field of usefulness was limited.

The modern method of sero-diagnosis rested upon Pfeiffer's discovery of the principles of artificial immunity, but Pfeiffer's reaction, so-called, had nothing directly to do with the reaction in serum immunity. The principle of Widal's test was that by the addition of one part of blood-serum to ten parts of fluid containing the typhoid bacilli a reaction takes place whereby the bacilli lose their motility and clump together. It had been ascertained by Dr. Wyatt Johnston of Montreal that this power of producing agglutination of the bacilli was retained by dried blood as well as fresh. Dr. Welch was of the opinion that the best method of obtaining the blood was by an incision, or by pricking the lobe of the ear, rather than by blisters or the opening of a vein. This power to cause agglutination of typhoid bacilli possessed by the blood-serum of typhoid patients was also possessed by other serous fluids, as the serum from a blister or the fluid from a serous cavity. High temperature destroys the power of agglutination. It is an open question whether more importance should be attached to the loss of motion of the bacilli or to the clumping, some observers being of one opinion and others holding to the opposite belief. Young cultures, not over twenty-four hours old, should be used in the tests, though still younger (from six to eight hours old) had been used with good results in some cases. He prefers a middle course, and uses and recommends cultures fifteen hours old. As to the culture medium, it did not seem to matter very much whether agar or bouillon was used. The use of old cultures is, he thought, a distinct source of error. The degree of saturation of the test was another point which should receive considerable consideration. With a strong saturation the reaction is obtained more quickly, while with a weak saturation a time limit of about two hours should be allowed. It was his experience that the reaction was more marked in thermostat-cultures than in room-cultures. The degree of saturation recommended by Widal was 1 to 10 or 1 to 15, but later experiments had shown that dilutions of 1 to 40 or 1 to 50 gave better results. The criticism had been made that the colon bacillus gave the reaction in some cases as strongly as the typhoid bacillus, but where there was any doubt in the differential diagnosis of the two diseases the precaution should be taken of making the test with a weak dilution, as the colon bacillus had never been known to react with a dilution greater than 1 to 40. Another source of difficulty in some cases is the late appearance of the reaction. In the majority of cases it could be obtained in the first week, but undoubted cases of typhoid, confirmed by subsequent *post-mortems*, had failed to give positive reaction until the second or third week, and in a few cases the reaction had been absent altogether. The conclusion to be drawn from this was that a negative reaction was not conclusive evidence of the absence of typhoid. A third source of error was to be found in the fact that the blood of persons who had had typhoid fever retained the power of agglutination for a considerable time.

He suggested that the discussion might very profitably cover the question of the utility of dried-blood preparations as against fresh specimens. While the former method possessed many advantages as a more convenient method, it lacked the quantitative exactness of the latter procedure. He thought it possible, however, that the method of examination with dried blood might be so developed as to furnish a qualitative test.

In conclusion, he laid stress upon the importance of precision in the test, but at the same time he thought the method might be so simplified as to be available for the general practitioner, so that a fairly accurate test might be made at the bedside. For the more exact examinations completely equipped laboratories were necessary and should be at the disposal of the general practitioner, and the establishment of such laboratories by cities or States should be encouraged.

He was followed by Dr. Wyatt Johnston of Montreal, whose experience with the serum test covered over 600 cases, more than half of them typhoid. He believed that other diseases, such as cholera and bubonic plague, would be shown to have a reaction. He had been led to devise the method of dried-blood tests on account of the distance that specimens had to be sent for examination, and it was found that the dried blood could be sent by mail. Dried blood, he thought, clumped more readily than serum.

The alkalinity of the culture was important, as, if it were acid, the reaction would not take place. Young cultures should be used in preference to old cultures. With proper cultures, if loss of motion took place without clumping, it might be regarded as a pseudo-test, or if clumping took place without complete loss of motion, the reaction should also be regarded with suspicion.

Dr. R. C. Cabot of Boston gave a

CLINICAL REPORT ON SERO-DIAGNOSIS.

The statistics of foreign and American observers which he had examined gave the following results:

In 1826 cases of supposed typhoid, 1740 or 95 per cent., autopsy, confirmed the serum test.

In 1649 cases *not* typhoid, 1592 (or 96 per cent.) were negative. Total, 3475 cases; 95.8 per cent. of which confirmed the serum test; 2 per cent. proved incorrect.

In the 101 cases supposed to be typhoid 96 had given positive reaction, while 5 had failed. Three of these were seen late in the disease. One was seen early in the disease, and persistently gave a negative reaction, though the *post-mortem* examination confirmed the diagnosis of typhoid.

In 301 cases, with diagnosis other than typhoid, 300 were negative, while 1 gave a positive reaction. This was a case of pernicious anemia in a negro. He had been in the habit of using dilutions of 1 to 10, which Dr. Welch and others had asserted was too strong, but his time limit was from fifteen to thirty minutes as against two hours. He used the quick, or microscopic method, in all his examinations. The phenomena necessary to constitute a typical Widal reaction were a cessation of motion and a clumping of the bacteria. With one of these elements present, and the other wanting, he would not call the case typhoid. For the purposes of statistics he had taken the first day in bed as the first day of the disease, and thought this method of calculation open to no stronger criticism than any other method of reckoning the beginning of an attack. The length of time which a patient who had once had typhoid would continue to show the reaction was *sub judice*, the longest period reported being thirteen years. Again, the reaction might be intermittent. Thus, it might be present one day, absent the next, present the third, etc.

The susceptibility of the blood of negroes to the test had been frequently referred to. Dr. Geo. B. Shattuck had examined the blood of seventeen negroes, and got positive reactions in two cases not known to have had typhoid, and in three others who had positively not had typhoid. One of these was the case of pernicious anemia above referred to. He thought the more careful tests should be made in a laboratory, but sufficiently accurate tests could be made at the bedside by the physician with a knowledge of bacteriology. The Widal test was certainly of very material aid in the diagnosis of typhoid.

Dr. Bloch of Baltimore discussed the subject, giving a clinical report on sero-diagnosis. Microscopic tests were made by diluting sixteen times. By means of the hemoglobinometer the exact amount of dilution could be determined. Examinations made at the same time with both fresh and dried specimens showed the results to be practically the same. The earliest date on which the reaction was obtained was on the sixth day, the first day of the disease being considered as that on which symptoms compelled the patient to give up work. One hundred and seven examinations in 46 cases of typhoid gave a percentage of failure of 6.5 per cent. The culture medium used was slighily alkaline, though experiments were made with acid and neutral media. The acid medium did not show any precipitate of dead bacteria. Especial interest attached to the use of the test in cases of tuberculosis. By this means it was possible to make a diagnosis at an early date in cases of tuberculous peritonitis, tuberculous meningitis, and even pulmonary tuberculosis. He gave the histories of several cases in which the diagnosis between tuberculosis and typhoid could have been made only in this way.

Dr. Gerhardt of New York, in the absence of Dr. H. M. Biggs, read a paper on

THE SERUM TEST FOR THE DIAGNOSIS OF TYPHOID.

The serum used in the tests by the New York Board of Health was obtained from blisters. The microscopic test was used whenever possible, the macroscopic seldom being resorted to. Dilutions of 1 to 10 were generally used. Cultures eighteen to twenty-four hours old and of great virulence were employed. The cultures were obtained from Pfeiffer. The distinctness of the reaction was more marked with virulent cultures. The medium might be agar on bouillon. The tests made in the laboratory of the New York Board of Health were generally made with dried blood with a 1 to 10 dilution and a fifteen-minute time limit. If positive reaction is obtained from these tests a positive diagnosis of typhoid is made, but if agglutination did not occur in fifteen minutes or required a greater dilution a request for a further test with serum was always made. There was a decided advantage in the use of serum obtained from a cantharidal blister. Others had suggested a dilution of 1 to 30 or 1 to 50 and a time limit of two hours, but there did not appear to be any advantage in this procedure.

DR. S. S. KNEASS of Philadelphia gave a brief clinical report on sero-diagnosis. There did not seem to be any connection between the virulence of the disease and the character of the reaction. The earliest date at which the reaction was obtained was on the fifth day.

A CLINICAL REPORT ON SERO-DIAGNOSIS,

by DRS. J. H. MUSSER and JOHN M. SWAN of Philadelphia, was read by DR. SWAN.

The tests were made with dried blood. One hundred tests were made. In 9 the blood was taken from children under 15, and in the remainder from adults; 26 from females and 74 from males; age and sex seemed to exercise no influence. The cases were divided into four classes: (1) Typhoid fever during the disease; (2) during convalescence from typhoid; (3) where typhoid had been present at some time, and (4) where typhoid had not been diagnosed. In the latter, the reaction was absent in all cases, among which were cases of pneumonia, tuberculosis, and catarrhal fever. His conclusions were: (1) that age and sex exercise no influence; (2) that the reaction might be obtained during the occurrence of the disease as early as the seventh day; (3) the reaction disappeared at varying periods after the cessation of the disease; (4) the reaction could not be obtained from blood taken from patients suffering from diseases other than typhoid.

DR. MARK W. RICHARDSON of Boston read a paper, entitled

ELSNER'S METHOD OF DIAGNOSIS IN TYPHOID FEVER.

Elsner's gelatin-culture medium had first been prepared with carbolic acid, but as a result of later experiments he had been led to substitute potassium iodid, and the inoculation of this gelatin with the stools of typhoid fever had been very successful. No other bacteria than those of typhoid fever could be made to grow upon this medium. He had been led to examine this method of testing for typhoid fever partly from a desire to see whether it would confirm the tests made with the blood-serum, and partly to see whether it could be relied upon in those cases in which Widal's test failed to give a reaction. The result of his investigations convinced him that the serum test was preferable on account of its greater convenience in those cases where it gave a positive reaction, but cases in which the serum test had failed might show a typical reaction by Elsner's method. An examination of twenty-nine cases other than typhoid showed no bacilli by Elsner's method, or the isolation of bacilli was imperfect. The statement made that the typhoid bacillus was an ubiquitous organism was not confirmed by this method as the examination of the non-typhoid cases had failed to show the presence of the bacillus.

He summed up his conclusions by stating that the value of Widal's serum test was greater by reason of its simplicity, but a case which had failed to react to this method might still show the typical typhoid reaction if the stools were examined by Elsner's method.

DR. N. S. DAVIS of Chicago said that according to his experience ninety per cent. of cases of genuine typhoid gave a positive reaction to the Widal test, and in six per cent. there was a partial reaction. In three per cent. of cases there was no reaction whatever. The time at which the reaction could be obtained varied, and had no relation to the severity of the attack. In two and one-half per cent. of the cases with clinical diagnoses other than typhoid, a reaction was obtained, but in all of these cases there was a history of a prior attack of typhoid. In view of the fact that the reaction was not a constant attendant of typhoid fever, he suggested that it would be more correct to call it a symptom of typhoid fever, rather than a test for typhoid. It stood in the same category as rose spots. When present with other symptoms of typhoid, these were of value. So it was with the serum test; it did not furnish conclusive evidence.

DR. H. A. WEST of Galveston, Tex., said that the test promised to be of especial importance in his section of the country, and he hoped it would be the means of settling the vexed question of diagnosis between typhoid, malaria, continued fever, thermic fever, etc. Many of these fevers failed to respond to the salts of cinchona, and he was of opinion that such cases were typhoid in character, and it was to be hoped that this test would clear up the matter.

DR. J. B. HERRICK of Chicago gave the experience of Dr. George H. Weaver, of the Rush Medical College, in the diagnosis of typhoid fever by means of Widal's test. Several of the cases examined had all the symptoms of typhoid fever, and were also tuberculous, and in these the test failed to give a reaction. It was possible that this failure of the test was merely a coincidence, but it opened up the question whether this test was applicable in cases of mixed infection.

Immediately after the Section was called to order for the afternoon session the following officers were elected for the ensuing year: Chairman, Dr. Fiske of Denver, secretary, Dr. Albert Jones of Buffalo.

DR. A. P. OHLMACHER of Cleveland read a paper, entitled

OBSERVATIONS ON TWO EXAMPLES OF TYPHOID MENINGEAL INFECTION.

The author gave the clinical and pathologic aspects of the cases. The spleen weighed 220 grams; the ileum was the seat of typical typhoid ulcers, and a hematoma was located in the brain substance. Cultures taken from the meningeal hemorrhage gave perfect growths of the typhoid bacillus.

The second case was like the first, but owing to lack of time Dr. Ohlmacher gave a brief synopsis of the two cases. Both gave clinical evidence of typhoid fever with suppurative leptomeningitis. Bacteriologic investigation gave large numbers of typhoid bacilli and of no other micro-organisms, while an exhaustive investigation of other organs furnished undoubted evidence that the cases were true typhoid. In the second case there was broncho-pneumonia as a complication, and typhoid bacilli, as well as staphylococci, were demonstrated in the lungs. There was also endarteritis of the cerebral arteries.

The next paper was read by Dr. William Osler of Baltimore, entitled

RELAPSES IN TYPHOID FEVER.

In 500 cases of typhoid fever treated in Dr. Osler's wards at the Johns Hopkins Hospital, there was a percentage of 8 per cent. of relapses, about the same as that noted by Liebermeister, but a much larger percentage than that given by Murchison. Physicians were apt to shift the responsibility for relapses to errors of diet, but it was his experience that error in diet was not responsible in any considerable number of cases. The term "relapse" should be limited to those cases in which there were distinct evidences of reinfections after a period of apyrexia. Rise of temperature and return of dangerous symptoms without a period of absolute freedom from fever and serious symptoms should be regarded as an intercurrent relapse and not as a true relapse.

The sources of reinfection were as yet unknown, but a possible source was the lingering of the bacilli in the mucous membranes of the system. Chiari also made the interesting suggestion that the typhoid bacilli remaining in the gall-bladder might become the source of a secondary infection. In nineteen out of twenty-three cases of typhoid fever Chiari demonstrated typhoid bacilli in the gall-bladder. Relapses might be single, double, or rarely, triple. Several cases where there had been four or five relapses had been reported, and Dr. DaCosta stated that he had had a case with five relapses. As illustrating the length of time a case of typhoid fever might continue, he related the history of a case in which, after a period of six-weeks' freedom from fever, a relapse occurred and later a second relapse, so that the original attack, with the two relapses, covered a period of six months. The relapses were not always of a similar character in their inception as the original attack, as the text-books used to teach. The fever did not increase by gradual steps, as the original fever did, but, on the contrary, might go up with two or three short bounds. In other cases the relapse might be the counterpart of the original attack. He did not believe that the Brand system of treatment had anything to do with the occurrence of relapses. The Brand method was used extensively in the wards of the Johns Hopkins Hospital, and the proportion of relapses there was not excessive, and no one could say, from a study of those records, that hydrotherapy had anything to do with such occurrences.

PERICHONDRITIS OF THE LARYNX IN TYPHOID FEVER was the title of the next paper read by Dr. M. H. Fussell of Philadelphia. The case of which this paper was a report occurred in a man thirty years of age, who came under his observation in December, 1894. There was considerable hoarseness, and the patient afterward developed pneumonia. After eating an apple he was seized with stenosis, and an examination showed an edema of the larynx, Perichondritis of the larynx was diagnosed, and tracheotomy was suggested, but the patient refused to have the operation done. He died on the seventh day, and the autopsy showed that there was a large perichondrial abscess. Hoarseness, with respiratory distress were the only symptoms complained of. The complication was very infrequent, but its infrequency did not excuse physicians and writers for neglecting it. The only treatment was tracheotomy.

Dr. H. A. West of Galveston read a paper upon

THE RATIONAL ANTISEPTIC TREATMENT OF TYPHOID FEVER.

He was skeptical of the value of the so-called abortive treatment of typhoid, believing, as he did, that this was a self-limited disease. Nor did he believe in the efficacy of the antiseptic treatment, for before the disease attained its height the bacilli would have passed through the intestinal tract into the blood, and no drug known could reach them there. His experience with the various "cures" recommended had not been such as to commend them to his judgment. The rational treatment of typhoid—the only antiseptic treatment—"begins at the mouth and ends at the bed-pan." The way to give antiseptics was to withhold anything in the way of food or medicines that would require any antisepsis, and to use the tooth-brush frequently for the dislodgment of particles of food that, accumulating in the teeth, might decompose and cause fermentation. One of the chief difficulties in the treatment of typhoid was the gastric disturbance which was generally a complication, for in no disease, except cancer of the stomach, was the power of the stomach to digest food so weakened as in typhoid fever. In typhoid fever the stomach might lose half its bulk. Added to this decrease in the amount of gastric juice there was also a decreased secretion of hydrochloric acid. For these reasons we should abstain from loading down the stomach with solid food which it could not dispose of, and the condition should be treated by the administration of pepsin, hydrochloric acid, and the like, which, in this case, were antiseptics in the proper sense of the word. It was now proved that the typhoid bacilli left the mucous membrane of the intestinal canal early in the stage of the disease and entered the blood, so that the administration of antiseptic drugs could have no effect upon them. In the rational treatment of the disease was included a plentiful supply of water to flush out the stomach, and good results follow copious irrigations of the large intestine.

The next paper read was by Dr. J. N. Upshur of Richmond, Va., upon

THE TREATMENT OF TYPHOID FEVER.

The author went into details as to the method of disinfecting bed-pan, bed-clothes, keeping the patient clean, etc. He deprecated the use of alcohol in the early stages of the disease, except in the cases of persons accustomed to its use. The headache, he said, required no treatment, for it would disappear spontaneously in the second week. Phenacetin might be used with caution, but in general the use of the coal-tar derivatives should be sedulously avoided. Bromid of soda should be given for sleeplessness, and for coma vigil there was nothing that could take the place of opium. Somnolence should be treated with alcohol. Nausea and vomiting were rarely of sufficient severity to require treatment, but when existing, drop doses of the tincture of iodin were useful. Constipation was not an indication of grave intestinal lesions, and laxative drugs were to be avoided. Salol should be administered when the stools were offensive, and sordes called for the internal use of turpentine. Strychnin, with nitroglycerin, should be given for a weak heart. Peritonitis demanded treatment with tincture of opium, or hypodermic injections of morphin, but celiotomy was not justifiable, as the probability of saving the patient was very slight. The bladder should be emptied frequently, either naturally or by the catheter.

He severely arraigned the abortive and antiseptic treatments in vogue as being thoroughly irrational. Woodbridge's method for the abortive treatment of typhoid made claims of such brilliant results that physicians were startled, and made them ask themselves the question whether they had been groping blindly in the dark up to this time. He confessed that he had never tried the treatment because he regarded his patients as of too much consequence to be subjected to such danger. With his knowledge of the disease and of its self-limited character, he could not understand the wonderful results claimed for the treatment by its originator unless the age of miracles had returned. The testimonials which had been filed regarding the efficacy of the treatment were of no more value than similar testimonials for some "cancer cure" or "kidney cure," and other "cures" *sui generis*. Considering the claim of Dr. Woodbridge that he had never had a death from typhoid fever since using his method, was it not strange, he asked, that no writer and no authority had ever recognized the treatment?

SECTION ON SURGERY AND ANATOMY.

SECOND DAY—JUNE 2D.

The meeting was called to order by the Chairman, DR. SAYRE.

The first paper was read by DR. CARL BECK of New York on the

TECHNIC OF PNEUMOTOMY.

He said that particular attention should be paid to the details of asepsis. The skin of the patient and the hands of the operator should be very carefully prepared, as well as all instruments, dressings, and other materials which may come in contact with the wound. As a rule, the eighth rib is selected. An incision about five inches long is made over the suspected area upon the rib. The periosteum is raised throughout the entire circumference of the rib, and the section of bone removed by shears. The muscles, fascia, periosteum, and pleural membrane are ligated by silk ligatures, which are passed by means of strong needles. The pleura is then divided. If the lung collapses the incision into the lung must be delayed for a day or two. If the lung moves freely, sterile gauze may be packed about the region to be operated upon to avoid infection of the cavity from escaping pus. If palpation fails to disclose the accumulation, the exploring needle may be thrust into the suspected area. If this does not reveal pus, then the slightly heated Paquelin cautery may be introduced in the direction of apparent trouble. After the cavity has been opened, irrigation and exploration should be avoided, as troublesome hemorrhage might result. A narrow strip of iodoform gauze is introduced into the cavity for drainage.

The speaker has operated upon four cases of lung abscess and all of the patients recovered. Anesthesia should be employed only if the pulse be strong enough, which is rare in these cases. Chloroform is usually to be preferred to ether if an anesthetic is used. In only one of the cases was the diagnosis of lung abscess made before operation. Two of the four cases had been diagnosticated as pyothorax, and the fourth was thought before operation to be a subphrenic abscess.

W. B. DE GARMO of New York reported

TWO HUNDRED AND FIFTY BASSINI OPERATIONS FOR THE CURE OF HERNIA, WITHOUT MORTALITY.

The 250 operations were performed on 216 patients. One patient was five months old and had a strangulated right scrotal hernia. There was also a scrotal hernia on the left side. Age is no contraindication to this operation, as the results have been as satisfactory in the aged as in the young. The success of Bassini's operation depends upon the removal of all superfluous tissue from the cord, and upon the formation of a new muscular floor for the canal. In the suppurative cases the infection seemed to have been superficial. In the cases in which the vitality of the tissues has been lessened by the pressure of a truss, infection is particularly apt to follow operation even when the most careful antiseptic details have been carried out. Contrary to the expectation of the speaker, the cases which suppurated had not shown a greater tendency to recurrence than had those which ran a sterile course. Silkworm gut was employed for the buried sutures in the earlier cases, but as the sutures caused irritation in a number of instances its use was discontinued and kangaroo tendon was substituted. The latter has proven entirely satisfactory. The author believes that ninety-five per cent. of the patients operated upon by this method will be cured even if observed for five years. Of the 250 operations there have been six recurrences and three patients are at present under suspicion. It has been possible to explain the recurrence in every instance. Two were the result of violence some time after the operation. One was the result of a varicocele that was not treated at the time of the herniotomy. In one case the muscles were in such an advanced state of fatty degeneration that the sutures failed to hold, and in two cases the patients took ether very badly, and the recurrence was due to undue haste in terminating the operation.

In the discussion **DR. H. O. MARCY** expressed his belief in a congenital defect as the cause of hernia. He thinks the presence of the infundibular process of Broquet allows of a slight protusion which gradually increases. He has operated on a child three months of age, and upon an adult in the eightieth year of life. He thinks that over ninety per cent. of his cases have remained cured.

DR. OCHSNER called attention to the patients with hernia who come for treatment at the two extremes of life. He has observed that patients who have worn a truss for years find that the hernia is not retained when the tenesmus and dysuria of prostatic hypertrophy become pronounced. In these cases he has adopted the operation recommended by Dr. White of Philadelphia, namely, either castration or ligation of the cord, with relief of the vesical symptoms, when the truss would again control the hernia. In the case of hernia in children he has frequently found the straining caused by phimosis to interfere with the cure of hernia, and in these cases the operation of circumcision has enabled him to cure the patient without a hernial operation.

In closing the discussion, Dr. De Garmo said that in the case of undescended testicle, if the cord is too short to bring the organ down into its proper position, he prefers covering it up with the muscular layer, outside of the peritoneum. He has had satisfactory results by this method.

A paper on

ANIMAL SUTURE, ITS PREPARATION AND TECHNIC OF APPLICATION,

by **DR. H. O. MARCY** was read by title.

After the meeting was called to order for the afternoon session, the following officers were elected for the ensuing year: Chairman, Dr. John B. Murphy of Chicago; secretary, Dr. W. D. Rodman of Louisville, Ky.; executive committee, Drs. J. Ransohoff of Cincinnati, C. A. Wheaton of St. Paul, and Reginald H. Sayre of New York.

DR. R. HARVEY REED of Columbus, O., read a paper on

ANCHORING THE KIDNEY.

The condition of floating kidney demands our attention, because it is apt to lead to hydro- or pyonephrosis. The use of abdominal bandages and pads of all sorts the speaker believes to be worse than useless. He has shown by experiments on the cadaver that no amount of pressure which could possibly be borne without injury will keep a movable kidney in place.

The operation which he advises is as follows: An incision two or three inches in length is made in the abdominal wall, anteriorly, over the normal situation of the kidney. Two or three fingers are introduced into the abdomen and the kidney replaced. The intestines are displaced to the inner side, and a suture of silk or other material, attached to a special needle six inches in length, is passed through the kidney-substance between the eleventh and twelfth ribs out through the lumbar muscles and skin. The needle is unthreaded and withdrawn. The other end of the thread is passed in the same manner a short distance from the point traversed by the first. The two ends of the suture are then tied over a small pad of gauze in the loin. These sutures are removed between the tenth and the fourteenth days.

He prefers this method to the usual lumbar operation on account of the ease and celerity with which the operation can be performed and the security of the results.

In the discussion **DR. THOMAS** of Pittsburg described a method of anchoring the kidney by splitting the fibrous capsule and dissecting flaps in each direction by means of which the organ may be very firmly fixed. This is done through the usual lumbar incision.

DR. J. B. DEAVER of Philadelphia read a paper on

THE COMPARATIVE MERITS OF DIFFERENT OPERATIONS FOR STONE IN THE BLADDER.

He prefers litholapaxy in all cases in which it is possible to introduce the necessary instruments. He operates, when possible, for stricture, and proceeds at once with the litholapaxy. In strictures of the deep urethra that require cutting, he performs the operation of perineal lithotomy and divides the stricture at the same time. If the stone is too hard or too large to crush he would perform suprapubic cystotomy.

DR. DEFOREST WILLARD and **DR. A. W. GOODSPEED** of Philadelphia gave a demonstration of the technic of the Röntgen rays, with its practical application to surgery, which was illustrated by means of stereopticon views. **DR. GOODSPEED** described the modern apparatus and its manipulation, and showed a number of views of normal structures which he claimed surgeons should be familiar with before they can properly interpret skiagraphs of abnormal conditions.

DR. WILLARD showed a number of photographs illustrating a number of conditions resulting from diseases and accidents. He called attention to the difficulty of interpreting many of the photographs when first presented. He did not think the skiagraph should be accepted at present in medico-legal cases in preference to means of examination which are better understood and more reliable. In common with other surgeons, he has made use of the X-rays in cases of fractures and dislocations, foreign bodies, bony outgrowths, inflammatory affections of the joints, etc.

SECTION ON OBSTETRICS AND GYNECOLOGY.

SECOND DAY—JUNE 2D.

The section convened at nine o'clock and was addressed by **DR. AUGUSTUS GOELET** of New York on

THE TECHNIC OF VAGINAL SECTION, EXCLUSIVE OF HYSTERECTOMY, FOR DISEASED APPENDAGES AND SMALL PELVIC TUMORS.

He claimed that anything that will lessen shock, reduce the mortality, and shorten the time of the operation, is to be desired, and all of these can be claimed for vaginal section. In certain conditions this operation is much to be preferred, although in some cases abdominal section is the better operation. The advantages of the vaginal route are: (1) The patient more readily consents to this operation, and therefore the diseased condition can be removed earlier. (2) It is of service when the condition of the patient does not seem to be grave enough to require the more formidable operation of abdominal section. (3) It is useful when an exploration of the pelvis becomes necessary in order to clear up a diagnosis. (4) The vaginal operation is best when subsequent drainage of the pelvis is required. It is applicable for small pelvic tumors, ovarian cysts after they have been evacuated, pyosalpinx, hydrosalpinx, and hematosalpinx; for the removal of small fibroids by myomectomy, for extra-uterine gestation, and for pelvic hematocele. The technic in the case of cysts is as follows: The pubes and vulva are thoroughly washed and shaved, and the vagina scrubbed out and irrigated. The patient is then placed in the exaggerated lithotomy position, the cervix is seized and dragged down by a volsellum forceps, and the uterus curetted and packed with iodoform gauze. The cervico-vaginal fold is the guide to the incision, which, starting at the central point, extends half way round the cervix to either side. Having opened the vaginal mucosa, the dissection is continued by means of the blunt edge of the knife. No effort is made to control the hemorrhage from the small vessels that may be cut, until the peritoneal cavity is opened. Then the peritoneal and vaginal fold are united by means of sutures, and the bleeding thus perfectly controlled. The pelvis is then explored and the diseased structures are drawn down, enucleated, and the pedicle ligated, the specimen being removed intact if possible. If it is too large to permit of this, it is drawn down as far as possible into the incision to avoid contaminating the surrounding pelvic structures, and then tapped and finally enucleated.

Dr. Goelet seldom uses a trochar. Irrigation of the vagina should be avoided if possible; when it is employed he uses only normal salt solution for the purpose. Prolapse of the intestine is prevented by means of gauze packing. Solid or semisolid tumors are more difficult of removal. In the case of larger fibroids he prefers abdominal section, although even these may be removed by morcellation. If the anterior wall is prolapsed in any given case the bladder must first be explored by a sound in order to precisely locate it and thereby prevent wounding of that viscus. The cervix, in opening the anterior cul-de-sac, should be drawn back and the incision made to hug it whereby wounding of the bladder may be prevented. If drainage is not required, the vaginal wound may be closed by sutures, although this is not necessary. If deemed necessary, a strip of sterilized gauze may be carried through the incision and packed around the stump to prevent the formation of adhesions to the intestines. This may be left in place for twenty-four hours and then withdrawn in part. The following day the fresh vaginal gauze and the remainder of the pelvic gauze is withdrawn. Union takes place in six days and the convalescence is usually uninterrupted.

DR. H. A. KELLY of Baltimore agreed with Dr. Goelet in all of his conclusions. He thinks vaginal section is preferable in all cases of relaxed vagina, or when the patient prefers it to the abdominal route. By this method he has treated small ovarian cysts, dermoid tumors, and pelvic abscesses almost without exception. He has tabulated nearly 100 such cases. He prefers here, however, the method of Edebohls, in order to maintain a sufficient avenue for free drainage. He secures this by means of an elliptic incision with the removal of a large crescentric piece of tissue. He also scrapes out the lining membrane of the abscess and then packs it with gauze, thereby securing healing by granulation without pus-formation. For extra-uterine pregnancy he prefers this method, especially in the old ruptured cases with pelvic hematoceles. He holds himself ready, however, to go ahead with an abdominal section in case of extreme hemorrhage. In the case of cystic ovaries, and the like, he prefers Pryor's method of inspection of the pelvic cavity, the patient being elevated and long retractors being introduced. He excludes from this treatment all cases in which conservative operations are intended. It is also not of service in cases requiring delicate manipulations.

DR. JOSEPH EASTMAN of Indianapolis has been interested in this method for some years. He emphasized some points in the technic and dwelt on the importance of Sims' posture in all vaginal operations. He said that he could not be induced to operate in the exaggerated lithotomy position. The cervix may be disinfected in the manner suggested in the paper, but still it is a source of infection and may infect the wound. He has never seen prolapse of the intestines occur when Sims' posture was used after a piece of gauze was introduced; nor in this position will infecting material pass up into the wound. He thinks a handlight is of more service than a headlight. He always has his assistant over-dilate the rectum first, so that the vulvar space is increased posteriorly. The Sims' speculum then retracts the relaxed tissue much more readily than other speculæ will do.

DR. HAGGARD of Nashville referred to the Graffe method of traction-ligature. The only objection to it, he said, was the difficulty met with in its introduction. Graffe first used this ligature in Emmet's service, and it has been used with success in other conditions in general surgery. Anterior colpotomy he claimed is at times more useful than abdominal section in fat women.

Dr. Goelet, in reply, said that the technic described in the paper is not meant to apply to incision for pelvic abscess. He admits that it is easier to do conservative work through an abdominal incision, and yet he can do some of it through the vagina. Infection from the cervix is more imaginary than actual. The cervix, by this method, is generally carried well out of the way. He did not see the advantage of the Graffe knot, and has always preferred the dorsal position for vaginal incisions.

DR. E. E. MONTGOMERY'S paper on

THE TREATMENT OF PUERPERAL SEPSIS

was read by title.

THE DESTINY OF VAGINAL HYSTERECTOMY FOR MALIGNANT DISEASE

was the title of a paper read by DR. LESTER C. HALL of Kansas City, Mo. He offered conclusions gleaned from personal experience and from the literature of the day. No tissue, he said, is more prone than the uterus to take on malignant degenerative processes. Lacerations due to childbirth and the presence of irritating discharges predispose thereto. In addition, irregular flow is believed by many women to be of common occurrence, and hence malignant conditions are often overlooked. Even a fetid discharge does not always excite apprehension and in these cases the invasion of the surrounding tissues not infrequently prevents the adoption of the operation of hysterectomy. As a result many of the cases that are thus presented are inoperable, at least by the vaginal route. The removal of infected glands and the surrounding infected tissue is, in his mind, impossible by the vaginal route; hence, we are compelled to look further for other methods of dealing with malignant disease. The method that admits of thorough inspection of the diseased parts and thus facilitates their removal will become the best method. He believes that vaginal hysterectomy will shortly be restricted to cases of early carcinoma limited to the cervix. Clarke's method is probably the operation that will become generally adopted for more advanced cases. The objection that has been advanced that this operation is too long and too tedious, will be overcome by the practice that makes perfect.

DR. JANVRIN of New York said he had been immensely interested in vaginal hysterectomy for the last fifteen years and had performed the operation many times. He is aware that many of the patients do come too late for cure, but he believes that the people are becoming educated in the matter and now are coming earlier than formerly. In the majority of his cases the operation has been done in the early stage before systemic infection has occurred and the value of the operation of vaginal hysterectomy he believes depends entirely upon this point. If the patients are seen before general infection occurs such cases can be operated upon thoroughly and with success. Thirty-three and one-third per cent. of his cases are living now at periods of three to fifteen years after the operation. If the disease has extended beyond the cervix, and much beyond the endometrium and into the peritoneal covering, these cases are not the subjects for vaginal hysterectomy nor for any other radical operation.

DR. EASTMAN does not believe vaginal hysterectomy is destined to obscurity. The relief from the symptoms and the prolongation of life is sufficient to justify the operation in each and every case, no matter how far advanced. By such means he believes we may also educate doctors to recognize the value of the earlier operation so that they will bring their patients at the proper operative period. The incision into the vaginal tissue should be free and should extend well beyond the diseased area. He also brings the pedicle down and fixes it within the wound where he can promptly see any return of the disease.

DR. DUFF of Pittsburg agreed with the last speaker in all that he had said. In operations done by him through the vagina he has had patients live from three to thirteen years; without the operation, they will invariably die within a year. The great point in the question is the fact that in the vast majority of cases the women have not only been careless themselves, but they have been informed by their attending physician that they were suffering merely from a change of life. He has never seen a woman who was healthy have any menstrual trouble during the period of the climacteric. He would impress upon the public the importance of frequent vaginal examination of all child-bearing women.

DR. MASSEY of Philadelphia desired to report a new and most valuable cure of cancer, *viz.*, the cataphoretic method, whereby mercuric oxychlorid can be diffused throughout the tissues and thereby destroy the malignant growth. He has the record of four out of eight cases that were so cured. He believes that this method will replace the vaginal operation. In employing it he uses, if necessary, a current of the strength of 1000 milliamperes.

DR. MARCY of Boston said that if we accept the theory that cancer is at first a local and then a general condition, we can have but one answer to the question as to the operative treatment, and that is, that vaginal hysterectomy is the proper procedure to adopt. Scarcely more than a decade since we first held that such an operation was the correct one, but the question now is, what are its limitations? The trouble formerly was that the local physician first tried his own application until the case had progressed too far for operation. This is fortunately not so common now. If the disease has become disseminated throughout the broad ligament it is quite another matter, and the operation is not possible.

DR. BOVEE of Washington entered a plea in the same direction that Dr. Marcy had indicated. Vaginal hysterectomy in his experience has been very beneficial in late cases. He has operated in such cases and some of the patients are still living, two years after the operation. The surgical operation accomplishes at one application what electricity does only after repeated applications, and the latter method permits of the possibility of the further spread of the disease in the intervals of treatment.

DR. DUDLEY of New York said that if the patient came with the uterus free, vaginal hysterectomy is the proper operation, but if there is intrapelvic disease and the uterus is fixed, or if the vaginal wall is involved, then an entirely different operation should be performed. The limitation of the disease must be first determined; if it is not limited to the organ the combined method should be used in order to accurately ascertain the extent of involvement. The destiny of vaginal hysterectomy will depend on these points.

DR. FREDERICKS of Buffalo called attention to the different rate of growth of various cancers. He has recently seen a case in which the cervix had been the seat of the growth for over seven years, and there is still but little extension. In any given case it cannot be determined whether the growth is going to be rapid or slow.

DR. KELLY believes that the destiny of vaginal hysterectomy is that it will be performed by the abdominal route, by which means the large wings of the broad ligaments can be removed and all the involved tissues dissected out. Preliminary catheterization of the ureters is the one essential feature in this operation to enable one to keep these organs under the finger and thereby avoid injuring them. He believes that many physicians cannot recognize cancer of the uterus even in its late stages. The immediate mortality of the Clarke operation is slightly greater than that of vaginal hysterectomy, but the ultimate results are better. He would insist upon repeated examinations of women who have borne children, beginning within four months after labor, and repeated at suitable intervals.

Dr. Joseph Price said that a discussion is very much smoother than an operation. In inoperable cases of carcinoma of the uterus, he uses the curette and the cautery, and the probability is that the patient will live for eighteen months or two years, or even more. He now operates on any case of cancer which comes to him. He prefers the vaginal route to all others. He has repeatedly removed half the vagina in these cases. He is also in favor of the use of clamps, which can be passed further away from the uterus than can any ligature. As to recurrences of the disease, they are usually to be found in the bowel and bladder, and in these cases the suffering is intense. Many of the cases which are operated upon, and in which the disease fails to recur, are in reality simply cases of erosion of the cervix.

The Nominating Committee, through Dr. Eastman, chairman, reported the following officers for the ensuing year: Chairman of the Section, Dr. Joseph Price of Philadelphia; secretary, Dr. Lester Curtis Hall of Kansas City, Mo.

Section on Diseases of Children.

Second Day—June 2d.

Dr. Louis Fisher of New York continued the discussion of diphtheria antitoxin by saying that he had been skeptical concerning antitoxin on account of the profession's experience with tuberculin. What he saw in Berlin in 1894, was only a repetition of what he had heard from Behring in 1891. In the summer of 1896 at the Children's Hospital, Bazinski told him that he no more dreaded diphtheria now than he did a case of ordinary constipation.

As the dose of castor oil in a given case of constipation depends on the cause, so does the antitoxin dose depend on the case. Some he saw, got well with 6000 units, others with a smaller dose, but as a rule a round dose of 2000 units is indicated in malignant cases.

All will agree that there is no fear as to the results. The membrane is thrown off in twenty-four to thirty-six hours. He had seen a case of malignant diphtheria, with fetor temperature of 101° F., which is considered a malignant low temperature, and pallor from the drenching of the system by septic elements. Here, as was his rule with all cases, the imperative indication was met first, the asphyxia relieved by a tube, and the antitoxin was then administered with little fear of the result if the dose is repeated when indicated.

He said that Dr. Jacobi had not been anxious to use the serum till others had tried it, but now, as he stated in his book, he almost considered it a crime not to use it.

Dr. Arnold of Pennsylvania had begun the use of antitoxin early and for a time all was auspicious; there were prompt manifestations of its beneficent influence in the separation of the membrane; the prognosis was in a measure positive, proved by the changes observed in the patients after an injection. After a year's use he had seen a case of diphtheria, used antitoxin, and the child died, though, before he saw it, the case was regarded as one of simple tonsillitis. Another case had an abnormally slow pulse—50, 45, 40—and death followed, and in another, death ensued from suppression of urine. The serum administered to these patients was from a reputable and prominent manufacturer, all of the same series and labels. The bacteriologist of this house had been loath to give any explanation of the occurrence.

Dr. Cook of Chicago stated that he would reply to the statement often made, that all cases recovering were evidence of a mistaken diagnosis. He reported a series of eighty-nine cases, with bacteriologic diagnoses, without a death, without intubation, and without a second dose of antitoxin. Perhaps fifteen were laryngeal cases, and several were severe. The necessity for intubation is like a boy with a whip driving a horse, he punishes the horse because he has it, so intubation is often done just because we have a tube.

Dr. Grafey of Ohio said the laity as well as the profession at large are shy of statistics when they are so large. He had seen an epidemic of diphtheria in which the laryngeal cases died promptly under ordinary treatment. The statistics, his own and other cases included in the series, showed 53 deaths and 47 recoveries. In another series he used antitoxin only for laryngeal cases, fourteen of sixteen patients recovered. He emphasized the importance of giving antitoxin early and repeating the dose if indicated.

Dr. McFarland of Philadelphia had administered some 3000 injections to animals. He mentioned that fact, as the trend of the discussion led to the opinion that the use of antitoxin was founded on an empiric basis. It rests on a scientific basis, worked out in the laboratory.

A definite amount of any serum protects a guinea-pig against a definite amount of toxin; five times the amount of toxin is neutralized by the same amount of antitoxin. It is certainly and absolutely an antidote to the diphtheria toxin.

Dr. Cox of Chicago emphasized the fact that the profession often neglected to ask at what temperature the serum was kept. It has been clearly demonstrated that it must be kept in a cool place, as it deteriorates at a high temperature.

Dr. Mayer of Johnstown, Pa., answered Dr. Coughlin, the essayist, who suggested punishment of children, if all else failed, in inducing them to take nourishment. The depressing effect of the punishment, added to the depressing effect of the disease, is much against recovery. He believed if ice cream is not too sweet it will do no harm. Stimulation, in his opinion, is essential. The purpose, limitation, and dosage of antitoxin apply as well to stimulants.

Dr. Withersteen of Minnesota reported twenty-five cases, with one death. In one family with ten children he had controlled the spread of it by isolation, and though the first patient was almost moribund, with a pulse of 140, it had recovered under use of antitoxin. New cases developed by the placing of a child in the infected room to sleep, and this emphasized the inefficiency of our present methods of disinfection. The prophylactic dose was administered in two cases with effect.

DR. HOUGHTON of Detroit said that in a series of 800 cases in Detroit, the antitoxin had been administered to 400, with a mortality of twelve and one-half per cent. in patients so treated, and thirty-four per cent. in those not so treated. He reported a case of sudden death in a young man, from fright, when seeing the preparation for the injection before it had been given. He had seen two epidemics in the Children's Free Hospital there; three cases, and thirty-four children exposed, with prophylactic injection limiting the cases to the original three, except in the house physician, who contracted the nasal form of the disease. Three subsequent outbreaks in different months were also checked. Three of the children to whom it was administered were three weeks of age. Only slight urticaria was noted in a few cases.

DR. LOUIS FISCHER of New York exhibited

A NEW INTUBATION TUBE AND INTRODUCER.

The recommendations are that he thus does away with an obturator and substitutes a rubber tube for the ordinary metal tube. The tube has been used in nine cases with perfect satisfaction, remaining in position in one case seven days. The tubes are so cheap that they can be burned after each case.

DR. ELLA E. BARNES of Birmingham, Ala., read a paper on

SOME CAUSES OF CONGENITAL DEFORMITIES.

She said more stress should be laid on preventative medicine. Deformities at birth are, as a rule, accounted for by some superstition, where they can and should be explained by anatomic reasons. Early injury to cells may result in large deformities. Later disturbances should not be considered true malformations.

DR. ANNIE S. DANIEL of New York read a paper, entitled

TUBERCULAR MENINGITIS.

The life of the patient, she said, does not depend on an early diagnosis, as no remedy has been found for the disease. Younger children presented greater difficulty in diagnosis. Lumbar puncture is negative, as a rule. Forty-nine cases were reported, with autopsies in six. They were divided into those under two years, twenty-two cases, and twenty-seven that were over two years. Previous acute illnesses were observed in the majority, and were chiefly intestinal troubles, exanthemata, etc. In many cases a fall is the result of the malady, and not as a cause, as generally considered, and should be termed a premonitory symptom.

A paper was read by DR. THOMAS W. MARVEY of Orange, N. J., upon

MENINGITIS, A COMPLICATION OF MEASLES.

He spoke of the rarity of mention in medical literature of meningitis occurring as a complication of measles. Brief mention was made of all the cases on record of this combination, and the history of an interesting case of meningitis complicating measles was given.

DR. A. E. DAVIS of New York read a paper, entitled

THE CLINICAL IMPORTANCE OF THE EYE SYMPTOMS IN ARRIVING AT A DIAGNOSIS IN MENINGITIS IN CHILDREN.

As conveyed in the title, the paper was to direct attention to the eye symptoms of meningitis. Many of the eye symptoms of importance in meningitis are largely motor, which may be observed without the aid of the ophthalmoscope. Thirty-eight cases of meningitis were reported; thirteen, simple leptomeningitis; twelve, cerebrospinal meningitis; thirteen, tuberculous.

In the thirteen cases of leptomeningitis there were no eye symptoms in eight. The patients with purulent meningitis, in which no eye symptoms were present, showed, *post-mortem*, the meninges covered with pus and extensive adhesions between pia and dura mater.

In the cases of cerebrospinal meningitis, eye symptoms were absent in seven. Loss of iris reflex was present in one, dilated and fixed pupils in another, strabismus in a third, and in the fourth the pupils were dilated, but reacted to light.

No eye symptoms were present in eight of those having tuberculous meningitis; pupils were dilated in one case, in one the left pupil only was dilated, in one there occurred extensive ulcerative keratitis and conjunctivitis, and in another dilated pupils and lagophthalmia. No tuberculous condition of the eye was seen in any case.

Whether symptoms are primary or secondary must be decided. The motor and visual disturbances should also be differentiated.

Cerebrospinal meningitis gives as prominent symptoms paralysis of sixth, third, fourth, ophthalmic division of fifth, and seventh nerves, with nystagmus and ptosis from cortical lesions. Choked disk, optic neuritis, perineuritis, plastic and suppurative iritis, conjunctivitis, edema of the lids, hemianopsia, as a cortex or tract lesion.

In simple or leptomeningitis the eye symptoms are of more importance in determining the diagnosis than in the cerebrospinal type. The most reliable is optic neuritis. Many cases occur as sequels to middle ear suppuration of a chronic character. Metastasis is another frequent cause. The neuritis is always consecutive to a complicating meningitis.

In tuberculous meningitis the eye symptoms are largely the same as in the simple form.

A paper was read by DR. CHARLES W. BURR of Philadelphia, entitled

HYSTERICAL CONTRACTURES IN CHILDREN.

Hysteria, he said, might be considered very frequent from literature, when in truth it is very infrequent, especially in children.

A case of pseudospinal disease was reported in a child six years old, with pain along the spine, trouble in walking, and lateral curvature. Pain on deep pressure was not present when the child's attention was withdrawn. Reflexes were good and there was no paralysis. The case was hysteric. Rest, isolation, and a milk diet cured the patient.

The second case was in a female of nine years. Barking like a dog and violence with irregular shrugging of shoulders were the first symptoms. These disappeared during sleep. No paralysis nor contraction of the field of vision was discovered. The same treatment was successful.

Girl, aged eleven years, had typhoid fever, pain in the hips and flexion of the thighs and legs. Force did not overcome the contracture. Pain was caused by passive motion. No palsies were present. All contractures relaxed, save in right hip, under anesthesia. Isolation and passive movements cured all but the right hip in which there was organic disease.

Dr. A. C. Cotton of Chicago read a paper upon

INFANT FEEDING.

He asked, How shall we feed the baby? If it takes the breast and is doing well let it alone. If not doing well find wherein the error lies; ascertain if the mother's milk can be made adequate, examine as to total amount, and its various ingredients. Analysis of the mother's milk must be made.

Marchand's and other tests for estimation of fat in milk was found to be wanting. Holt's method is not practical. The best method is Babcock's, although it is clumsy. By taking specific gravity and amount of butter fat we have two factors. Allow equation—total solids equal ¼ of specific gravity, taking last two figures, and $\frac{6}{5}$ of fat plus 14.

If milk shows marked departure from normal try to regulate, meanwhile, pumping breast and testing frequently.

The multitude of artificial foods is evidence that we have no substitute for mother's milk. The ideal one must contain all elements of mother's milk, in like proportion. Total quantity must equal that obtained from the mother. That it contain the antiscorbutic element, and be always fresh, are essential.

Dr. Charles G. Kerley read a paper on

THE USES AND LIMITATIONS OF CONDENSED MILK AS AN INFANT FOOD. (See page 736.)

The Nominating Committee reported for Chairman, Dr. J. P. Crozer Griffith of Philadelphia; Dr. Edwin Rosenthal of Philadelphia, Secretary.

Section on Neurology and Medical Jurisprudence.

Second Day—June 2d.

The entire session was devoted to the reading and discussion of a very scholarly paper by Dr. Charles K. Mills of Philadelphia on

APHASIA.

Dr. Mills said: "I would enlarge the zone of language, as given by Dejerine, so as to make it include a center for concepts in the third temporal convolution, and possibly extending over more of the mid-temporal region, and, in addition, a graphic motor center in the caudal portion of the second frontal convolution. This zone of language unquestionably has its deepest organization and highest development in the region encircling the Sylvian fissure, for here is situated the auditory center, out of which the others may be said to have been evolved, and the motor, articulatory and visual centers which are next in importance, as they have been next in development; but it must also include those portions of the brain in which concepts originate, and, if the views of those who believe in separate graphic motor centers are correct, also those parts in which graphic motor images are represented. Moreover, language on its productive side may result from impressions received through any of the sensory gateways. Written and spoken language is evoked not only by auditory and visual images, but also through olfactory, tactile, gustatory, and spatial percepts, so that in a lesser degree the centers for touch, taste, smell, and other senses than those of audition and vision, and the tracts which associate these centers with the motor side of the brain, may be regarded as properly constituting, at least at times, a part of the zone of language. . . .

"Ross held that in passing from thinking by precepts to thinking by concepts, and from that to thinking by abstracts, no new centers are introduced, but only complication upon complication of the precept center or centers. The evolution of such a complex mechanism, however, necessitates the enlargement of the sensory precept areas, and this would have as its particular result the development of a new structural area intercalated between the receptive and the emissive portions of the brain, but more closely related to the former than to the latter. When lesions occur near, but not in, the sensory inlets, a disorder of language, conceptual in character, results. The portions of the cortex, the activity of which is related to thinking by concepts and abstracts, can be reached in the word-blind through the eye, in the word-deaf through the ear, and in those who cerebrally are both deaf and blind through the nerves of the other special senses. If this be so, in some region of the brain the structural lines must converge, or at least commingle, and cross on their way from the sensory centers to the motor centers, and this area, however restricted or extended, constitutes the *concept region of the zone of language.* The symtomatology which results from a lesion of this concept area is that which was present in the case reported by the writer as localizing this naming or concept center. The patient was unable to recall through either the sense of sight or that of touch the names of objects, the uses of which she evidently recognized."

Dr. Mills referred to a case the symptoms of which seem to bear out the idea of the existence of a separate graphic center. This patient has disturbances of language which have been of gradual development. He is not word-deaf, he is not a true motor aphasic, but he is a total agraphic. He is only able to copy mechanically printed letters or words. At times he seems to have great difficulty in recognizing words or special letters; so that it is difficult to decide whether he is suffering from literal or word-blindness.

According to Freud, the so-called centers, placed in the periphery of the zone of language, are only points farthest removed from other centers, where, therefore, the fibers of association are least abundant and where a localized lesion is more likely to include only a single element of language. But in Dr. Mills' opinion, mistakes are likely to be made as regards both centers and associating systems. The use of the term "centers" in neurology, while important, is largely a matter of convenience. A center is simply a collection of gray and white matter which represents, physiologically, some action, function, or faculty. Its destruction causes loss or impairment of function, and its irritation leads to excess of functional activity. Centers, like cells, are too often considered as points where force originates. They are best regarded simply as points in reflex arcs or in systems of association, interference with which causes definite phenomena. Impulses are transmitted from nerve-cell to nerve-cell by contact, and not by continuous fibers over distances indefinitely prolonged. It is an error to make too great a distinction between the effects of lesions of association tracts and of centers. Center and tract each plays its own important *rôle*, and it is for us simply to learn, through clinical and pathologic observations, the results caused by their lesions when these are of definite size and in definite locations.

DR. F. X. DERCUM of Philadelphia opened the discussion. He agreed with Dr. Mills that the subject should be approach from a very broad and general standpoint. He had many years ago himself alluded to the various centers of the cortex as gateways of ingress and egress to the general cortex, and also contended against the consideration of centers as centers. He, Dercum, thought it not impossible that there is a concept or name center, but he did not regard it as proven. As to the graphomotor center, the same would seem to be true. He agreed with the author of the paper that the apparatus must be looked upon as a whole, and of course if there is a lesion in the commissural tracts there will be aphasic symptoms; but it is very difficult, even when the lesions are supposed to reside in the centers, to isolate one from the others.

DR. HUGH T. PATRICK of Chicago was inclined to agree with the views of Dejerine, and those who would locate the various departments of speech in a more diffused manner over the various regions of the cortex.

DR. WILLIAM G. SPILLER of Philadelphia spoke of a case of tactile aphasia. In this form a person does not recognize what he has in his hand. The patient may even be able to describe the object very exactly, but is unable to name it.

The Chairman thought a broad distinction might be drawn between cases of aphasia resulting from defective ingoing impressions and faulty outgoing motor impulses; that aphasias should be characterized as fundamental aphasias and as conceptional aphasias. There are unquestionably certain aphasias produced by impairment of the primary seats of ingoing and outgoing cavities of the brain, while there are other aphasias which are due to trouble of the higher, or the conceptional, or the associated cavities of the brain

DR. CARPENTER also discussed the paper, and mentioned several experiments which he had made upon rabbits with fine platinum electrodes and the very mildest currents, for locating the chewing center. He found marked variations in different rabbits. Just forward from the chewing center was the lip center, and there was a line which produced both lip and chewing movements, and beyond this the lip region was distinctly located.

DR. FULLER suggested that the resulting symptoms would depend very much upon the extent of the lesion. If a blow was struck with a club, for instance, it might go down exactly at the point of the angular gyrus, whereas if it were a little beyond it would push upon the longitudinal commissure, and if it where a little deeper it would cut off the ingoing fibers.

GENERAL SESSION.

THIRD DAY—JUNE 3D.

After the reading of the minutes of the previous session, an announcement of the program of the day was made by **DR. H. A. HARE**, Chairman of the Committee of Arrangements.

A resolution recommending the formation of a National Medical Aid Association was referred to the Publication Committee for consideration. The annual report of the Board of Trustees was then read by **DR. E. E. MONTGOMERY** of Philadelphia. It showed that there is a cash balance in the treasury of the Association of $7160. Receipts from advertisers in the official *Journal* have been greatly reduced during the past year, this being attributable, it is said, to the publication of formulæ in the advertising pages. Anent the discussion which has recently taken place regarding the advisability of moving the publication headquarters from Chicago, the Board recommended that no change be made. A warm tribute of praise was paid to the present editorial staff, through whose unceasing efforts the standard of the *Journal* has been maintained and its circulation greatly increased during the past year. It was recommended that the Board of Trustees be incorporated in order that it might expedite the settlement of certain legal matters now pending.

DR. W. W. KEEN of Philadelphia then delivered the

ADDRESS ON SURGERY. (See page 727.)

During the reading of this address the Presidents of the State Medical Societies and the Presidents of the State Boards of Medical Examiners had assembled in the Green Room of the Academy to meet Dr. N. S. Davis of Chicago, one of the founders of the Association, and upon its completion he was escorted to the stage. Among those accompanying him were Drs. T. J. Smith of New Jersey, Rienzi Robinson of Connecticut, J. W. Gilbert of Mississippi, Charles Phelps of New York, P. S. Murphy of North Carolina, F. C. Larimore of Ohio, George B. Johnston of Virginia, George H. Noble of Georgia, J. H. Duncan of Missouri, J. M. Matthews of Kentucky, W. H. Sanders of Alabama, Hiber Jones of Tennessee, and Wm, C. Riddell of Montana.

Dr. Davis was introduced by Dr. John B. Roberts of Philadelphia, who gracefully expressed the pleasure and honor of the members of the Association at thus having the opportunity of welcoming him, The President, Dr. Senn, followed with a brief address of like tenor.

Dr. Davis' address dealt with the origin and historical aspects of the American Medical Association, its principles and objects, and the results which have been accomplished by the organization. He spoke at some length on the early progress of the Association, in particular from its incorporation to a period covering the first decade of its existence. He then took up the subject of early medical instruction in America, pointing out its lamentable crudeness and contrasting this with the regulations governing and the opportunities offered for the study of medicine at the present day. After tracing the growth of American medical education and deprecating the rivalry existing between medical schools, which leads in some instances to the lowering of a medical degree beneath the level of a common apprenticeship, he closed with an exhortation to the members to advance the work steadily along the lines established by the founders.

At the close of Dr. Davis' address, Dr. Roberts announced that besides Dr. Davis, three other founders of the Association were now living, all octogenarians—Drs. Alfred Stillé of Philadelphia, David W. Atwater of Massachusetts, and J. B. Johnson of St. Louis. Letters of congratulation and regret from Drs. Atwater and Johnson were read, each evincing the warm heart and vigorous mind of the writer.

An address, entitled

WHAT STATE MEDICAL SOCIETIES HAVE DONE FOR THE PEOPLE,

was then read by Dr. George Ben. Johnson of Virginia, and was followed by one on

STATE BOARDS OF MEDICAL EXAMINERS; WHAT THEY HAVE DONE, HOW THEY SHOULD BE MADE UP, AND WHAT THEY SHOULD DO,

which was read by Dr. Wm. Perry Watson of New Jersey.

The following were chosen as officers of the Association for 1898: President, George M. Sternberg of Washington; vice-presidents, first, Joseph M. Matthews of Louisville; second, J. L. Thompson of Indianapolis; third, F. H. Wiggin of New York; fourth, T. J. Happel. Treasurer, H. P. Newman of Chicago; secretary, Wm. B. Atkinson of Philadelphia; chairman, committee of arrangements, J. W. Graham of Denver; librarian, George W. Webster of Illinois. Board of trustees: Jos. Eastman of Indiana, J. F. Priestly of Iowa, Truman W. Miller of Illinois, term expires in 1900. Judicial council: All the former members were re-elected, their terms to expire in 1900. J. H. Musser of Philadelphia was elected to deliver the address on "Medicine;" John B. Murphy of Chicago that on "Surgery," and Samuel C. Busey of Washington, D. C., that on "State Medicine" at the next meeting. Denver, Colorado, was chosen as the next place of meeting.

(To be concluded.)

SOCIAL FEATURES OF THE MEETING.

No general excursion was indulged in by the Association as a body, but many pleasant visits to various points of interest were enjoyed by extemporized parties, the most important of which was a trip to Atlantic City, by invitation of the medical society of that seaside resort. Luncheons were provided in several different places each day, so that the crowd could be somewhat distributed, but even this forethought did not entirely prevent the usual struggle for the means of sustenance. The stated dinners of the various sections were all held simultaneously on Tuesday evening.

The dinner of the Section on General Medicine was held at the Aldine Hotel. The members occupied the large banquet-hall, which was profusely decorated with flowers; the guests numbered over one hundred, and included the leading medical men in attendance at the convention. While no set speeches were on the program, extemporaneous addresses, in response to the call of the toastmaster, Dr. John H. Musser, were made by Surgeon-General George M. Sternberg, U. S. A., Dr. Wyatt Johnston of Montreal, Dr. N. S. Davis, Jr., of Chicago, Dr. D. A. Fiske of San Francisco, and by Drs. H. C. Wood, H. A. Hare, and William Pepper of Philadelphia. Among those in attendance were Drs. Wm. Welch, C. F. Hoover, J. B. Lindsey, S. A. Knopf, J. M. Upshur, H. M. Bracken, H. J. Herrick, J. B. Herrick, Elmer Lee, F. B. Turck, R. C. Cabot, and the following from Philadelphia: S. Solis Cohen, Alfred Stengel, D. M. Hamill, J. D. Steele, J. P. Arnold, D. L. Edsall, Boardman Reed, D. D. Stewart, H. S. Anders, Thos. G. Ashton, Jas. Tyson, A. C. Abbott, M. H. Fussell, A. A. Stevens.

The dinner of the Section on General Surgery was held at the Hotel Bellevue. Among those present were Drs. L. A. Sayre, R. H. Sayre, W. B. Coley, New York; J. McFadden Gaston, Atlanta; E. Souchon, New Orleans; H. A. Kelly, Baltimore; Hunter McGuire, Richmond; H. O. Marcy, Boston; Carl Beck, New York; and from Philadelphia, Drs. Orville Horwitz, E. Laplace, R. G. La Coute, R. Farias, J. B. Roberts, J. K. Young, J. William White, J. Chalmers DaCosta, and W. J. Hearn. Speeches were made by Drs. Nicholas Senn, John Ashhurst, Jr., Hunter McGuire, H. O. Marcy, and G. R. Fowler. Dr. Orville Horwitz, who acted as toastmaster for the occasion, also made some particularly felicitous remarks.

The Section on Obstetrics and Diseases of Women held its banquet in the large banquet-hall of the Hotel Walton, covers being laid for two hundred guests. Dr. Joseph Eastman of Indianapolis was introduced as the toastmaster of the evening by the Chairman of the Committee of Arrangements, Dr. M. B. Ward, and proved to be a most genially disposed presiding officer for the occasion. Toasts were responded to by Drs. Theophilus Parvin of Philadelphia, M. B. Ward of Topeka, Kan., Joseph Price of Philadelphia, L. S. McMurtry of Louisville, Ky., W. E. B. Davis of Birmingham, Ala., E. E. Montgomery of Philadelphia, H. P. Newman of Chicago, L. H. Dunning of Indianapolis, T. H. Manley of New York, and C. A. L. Reed of Cincinnati.

The dinner of the Section on Pediatrics was held in the banquet-room of the Philadelphia Bourse Building, at which a large number of the members interested in the diseases of children were present. Dr. J. P. Crozer Griffith of Philadelphia delivered an address of welcome, and then introduced the toastmaster, Dr. John A. Larrabee, the chairman of the section. Among those present at the dinner were Drs. E. E. Graham, E. Rosenthal, W. A. N. Dorland, J. A. Larrabee, J. P. Crozer Griffith, A. C. Klebs, W. W. Gray, Louis Fischer, H. C. Bloom, C. H. Reckufus, W. H. Wells, W. Reynolds Wilson, Clara Dercum, Bertha Lewis, Kate Baldwin, Anna Fullerton, Frances Van Gasken, Mary Jones, Gertrude Walker, Ada Audenried, J. Madison Taylor, A. E. Gallant, and H. E. Tully.

The dinner of the Section on Dermatology and Syphilography took place at the Hotel Walton, and was well attended by those interested in this branch of medicine. Dr. D. A. Ravogli of Cincinnati presided as toastmaster, and introduced Drs. L. Duncan Bulkley, S. Politzer, J. A. Fordyce, and J. Abbott Cantrell, who, among a number of others, made speeches. The following were among the guests of the evening: Drs. J. F. Schamberg, M. B. Hartzell, J. A. Fordyce, J. Abbott Cantrell, I. M. Koch, R. A. McDonnell, J. W. Lord, William B. Ewing, John V. Shoemaker, L. Duncan Bulkley, A. Ravogli, J. Edward Stubbert, Charles W. Allen, R. R. Campbell, Henry Fleischner, William M. Baum, and T. Casper Gilchrist.

The Section on Ophthalmology banqueted at the Hotel Walton, about eighty members participating in what was declared generally to be the most successful dinner ever given by this body. Dr. George E. de Schweinitz, who acted as the toastmaster of the evening, introduced many of the members, and was himself one of the most happy speakers of the occasion. The principal address was made by Dr. William Thomson, emeritus professor of ophthalmology in the Jefferson Medical College.

The dinner of the Section on Dental and Oral Surgery was held at the Continental Hotel, over sixty guests being present. The toastmaster was Dr. D. H. Guilford, who introduced as speech-makers of the evening Drs. R. R. Andrews, E. T. Darby, E. S. Talbot. J. Truman, W. F. Litch, C. M. Pierce, J. T. Marshall, G. F. Eames, and G. V. Brown.

The Section on State Medicine banqueted at the Aldine Hotel, and the Section on Laryngology, Rhinology, and Otology at the Stenton.

A reception and luncheon was tendered the Section on Laryngology, Otology, and Rhinology by the Board of Directors of the Howard Hospital. After an introduction by the president of the board, Mr. Azariah W. Hoopes, Dr. Laurence Turnbull spoke in an interesting manner of the inception and growth of the institution, and detailed the present work of the hospital in its several branches. The president of the medical board, Dr. William B. Atkinson, then briefly remarked on the historical aspect of the medical profession in Philadelphia, and was followed with short but timely addresses by Dr. T. S. Harper, a founder of the institution, Drs. W. E. Castleberry and E. Fletcher Ingals of Chicago, J. Fulton of St. Paul, G. V. Woolen of Indianapolis, and D. Braden Kyle of Philadelphia.

The various receptions held Wednesday evening were very largely attended and proved most enjoyable. The Provost and Faculty of the Medical Department of the University of Pennsylvania received at the Union League. Dr. John Marshall presented the visitors to Provost Harrison, who, in turn, passed them on to the gentlemen and ladies who assisted him in receiving. The large banquet-hall at times was even uncomfortably crowded.

The Dean and Faculty of Jefferson Medical College held a reception at the Academy of Fine Arts. The reception committee included the Dean, Dr. J. W. Holland, and Drs. John H. Brinton, W. W. Keen, and James C. Wilson. Music by a large orchestra was a feature of the evening. Refreshments were served in the lecture-room, which was beautifully decorated with American beauty roses, pink and white peonies, and ferns.

Many of the visiting delegates and their wives were entertained at the Medico-Chirurgical Hospital by the trustees at a reception which was held in the rotunda of of the hospital. The new clinical amphitheater, which is one of the largest and finest in the United States, was thrown open for inspection, as were the rest of the hospital buildings. In the new building, the private operating-rooms, and the magnificent amphitheater, as well as the surgical equipment, were the subject of most favorable criticism, Refreshments were served during the entire evening in the Board rooms as well as in the rotunda, and the members of the hospital faculty were untiringly watchful of the comfort of their guests.

Governor Hastings and Mrs. Hastings and President Senn and Dr. John B. Hamilton were among those who accepted of the hospitality extended by the hospital, and the following members of the Board of Trustees constituted the Reception Committee: Drs. C. William Bergner, W. Frank Haehlen, John V. Shoemaker, James M. Anders, Ernest Laplace, W. Easterly Ashton, and L. Webster Fox.

Dr. John V. Shoemaker and Mrs. Shoemaker entertained Governor and Mrs. Hastings, and the members of the Association, at a reception at their residence, 1519 Walnut street. A large number were present during the entire evening, among whom were many of the State legislators. A supper followed the reception.

There was a crush of visitors during the whole of the evening at the reception given to members of the Association at the Woman's Medical College—the first college established for the education of women in medicine—and the gathering was notable for the predominating presence of the fair sex. Among the latter were visitors from California, New York, Massachusetts, Connecticut, and Georgia, and other Southern States.

The hospital was prettily decorated with the college colors of red and gray, Spanish moss representing the latter shade among the flowering and foliage plants that ornamented the lower floor and main staircase. The members of the Faculty, constituting the Reception Committee, were the Dean, Dr. Clara Marshall, and Drs. Anna E.

Broomall, Hannah T. Croasdale, William H. Parish, John B. Roberts, Elizabeth R. Bundy, S. Barton, Anna M. Fullerton, and the Sub-dean, Dr. Ruth Webster Lathrop. The Woman's Hospital, adjoining the college, was also thrown open for the inspection of visitors.

On Thursday a number of enjoyable luncheons were given. The Obstetrical Section of the Association was entertained at the Hotel Stenton, and the Pediatric Section at the Children's Hospital, South Twenty-second street. Dr. W. W, Keen entertained the Surgical Section at the Hotel Walton, Dr. J. H. Musser the Medical Section at Houston Hall, one of the University buildings, and Dr. L. Webster Fox the Ophthalmic Section at the Hotel Bellevue. From six to seven o'clock, Provost and Mrs. Harrison received at a garden party on the campus of the University of Pennsylvania. Thursday evening was devoted exclusively to the theater-party given by Messrs. Lea Brothers & Company to the delegates and accompanying ladies. The list of interesting vitascope pictures proved a source of great entertainment and delight.

The excursion to Atlantic City on Friday was participated in by a very large number of delegates and their wives. A special train on the Philadelphia & Reading Railway left Philadelphia at 5.30 o'clock in the afternoon, the return train leaving Atlantic City the following afternoon at the same hour. Dr. Joseph F. Edwards of Atlantic City, Chairman of the Entertainment Committee, had the matter in charge, and to his untiring efforts, which were ably seconded by his colleagues, the great success of the excursion was due.

The ladies visiting the city with the members of the Association were given a round of pleasure and sightseeing by the ladies of Philadelphia. The New Century Club was thrown open to them, and there they assembled at nine o'clock each morning and decided to which of the many points of interest they should go in small parties, each attended by one of the reception committee as a guide. There have been receptions by the Colonial Dames, by the Ladies' Committee of the Jefferson College Hospital, by the Mayor and Mrs. Warwick, etc.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Eleventh Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

First Day—May 4th.

The President, Dr. Francis S. Watson, of Boston, in the Chair.

Before taking up the scientific work of the meeting, the President, Dr. Watson, made a brief address, in the course of which he called attention to the large amount of new and valuable material that is annually contributed by the members of the Association to this branch of surgery, a field which, before the Association was formed, was thought to be already quite thoroughly explored and cultivated. He suggested that each year some special subject should be taken up for individual investigation, and the results reported at the next annual meeting.

Dr. Watson read a paper, entitled

A REPORT OF POST-MORTEM EXAMINATIONS IN SOME CASES OF MOVABLE KIDNEY.

It consisted of a report of the *post-mortem* appearances in eight cases of movable kidney. Four of these subjects were males; four females. In four of them both kidneys were movable. The right kidney alone was movable in three cases; the left kidney alone in one case. Hydronephrosis was absent in all of the cases. There was ptosis of one or more of the other abdominal organs in six cases; none in two. The peritoneal coverings of the kidney were greatly relaxed in four cases and moderately relaxed in four. In two of the first four cases, those in which the peritoneum was greatly relaxed, the kidney rotated upon its long or short axis upon turning the body on the side opposite to that of the mobile kidney, or raising the body to an upright position and then bending it far forward.

An interesting point brought to light by these observations was the absence of serious consequences attributable to the movable kidney. In none of them was there evidence of dilatation of the pelvis or the calices of the kidney, or of any organic change that could be referred to the presence of a hydronephrosis during life, and this was as true of those in which the condition was of long standing and the motility very marked, as in the others. This fact he had also observed in five other cases in the living subject on whom he had performed nephrorrhaphy.

The speaker's observations in these thirteen cases confirmed the view recently expressed by Albarran that at least in the earlier stages of movable kidney the enlargement of the organ so often noticed in connection with the crises is due to acute congestion rather than to retention of urine in the renal pelvis, and subsequent dilatation.

Dr. John P. Bryson of St. Louis followed with a paper upon

CLINICAL OBSERVATIONS OF LOOSE AND DISPLACED KIDNEYS.

These observations had been made in the course of operative work in this field, and only represented a synopsis of what the speaker intended to do finally in this connection.

The real pathologic entity in the condition of loose or displaced kidney is a disturbance in the fatty capsule; whether or not this is accompanied by a more or less general enteroptosis was uncertain. There exists, first, a loosening of the capsule, which allows the kidney to move about within it; second, the capsule itself may become loosened from its posterior and superior attachments in such a way as to slip about with the kidney; third, these abnormal conditions may be combined in a greater or lesser degree.

A good deal of the pain and distress which exists in these cases of loose kidney is due to the relative length and looseness of the vascular pedicle. In the cases of displaced kidney the symptoms varied considerably. In some cases there were no symptoms at all referable to the kidney. In one case, which proved to be a displaced right kidney pressing on the duodenum, the symptoms were entirely gastric in character. Vomiting had never been observed in connection with disturbance of the left kidney, whether due to calculus or other cause, while with disturbance of the right kidney vomiting was very common.

Dr. **George E. Brewer** of New York read a paper upon

SOME OBSERVATIONS UPON THE SURGICAL ANATOMY OF THE KIDNEY.

This will appear shortly in the columns of the News.

RESULTS AFTER NEPHRECTOMY FOR RENAL TUBERCULOSIS.

Dr. **L. Bolton Bangs** of New York made a few remarks on this subject. He stated that he had recently made a careful search of the literature, and obtained the experience of his surgical friends, in order to learn, if possible, what the remote results of nephrectomy for renal tuberculosis were, and how they compared with those of hygienic measures. In many cases it was difficult to obtain this information, as the patient had been lost sight of. The literature was searched as far back as 1888, when Newman made his report on this subject. Since then, by the aid of the cystoscope and ureteral catheterization, the diagnosis of renal tuberculosis has become much more exact. He had collected 112 cases, most of which have not been included in any previous report on the subject. The mortality of the operation was about nineteen per cent., adding to this those cases that died within a few months after the operation, we get a mortality of twenty-eight per cent. Thirty-three of the 112 cases (about thirty per cent.) survived for a period varying from one to eight years after the operation. Twenty-eight of the 112 cases were alive nine months after the operation, and in thirty-three cases the result was stated as "promising." As regards the remote results, therefore, a good prognosis was given in about fifty-five per cent. of the cases operated on. In nineteen cases the remote result could not be ascertained.

A study of the above cases shows that the immediate result of nephrectomy for tuberculosis of the kidney may be said to be brilliant, and the prognosis as to the future, especially if the disease is of short duration and confined to one kidney, is very promising.

Dr. **Edward Martin** of Philadelphia read a paper on

DETECTION OF STONE IN THE KIDNEY.

He stated that the following points should be considered in making the diagnosis of kidney calculus: Family history, age and environment, traumatism, diathesis, kidney lesions, whether obstructive or otherwise, the presence of certain elements in the urine (among these an abundance of mucus, blood, crystalline deposits in excess, pus, epithelium, and albumen), alterations in the quantity and specific gravity of the urine, pain. one of the most constant symptoms, although very misleading, tenderness on deep palpation, the presence of a tumor. This he stated is only appreciable after pyonephrosis has developed and multiple calculi of large size had formed. Gastro-intestinal disturbance must be considered, also reflex disturbances of the lower urinary tract. Palpation may be an aid in some instances, although in his own experience he has been unable to make out the kidney in a large per cent. of cases. Ureteral examination affords valuable information. But the X-ray promises to become our most valuable means of diagnosing (*a*) latent cases of calculus; (*b*) those with the regular symptoms; (*c*) to distinguish between renal stone and such conditions as tuberculosis, acute congestion, Bright's disease, nephralgia, and kidney abnormalities giving rise to symptoms identical with stone.

Of the symptoms and signs above enumerated, Dr. Martin said he should place in the order of value:

1. X-ray photographs. Of these several should be taken with the light placed somewhat differently before their negative evidence is accepted.
2. The passage of gravel or small concrements, associated with renal hematuria, fixed pain and colic.
3. Renal hematuria, aggravated by exercise, markedly relieved by rest, remaining long unassociated with pyuria.

After concluding his paper, Dr. Martin exhibited a number of negatives of X-ray photographs, showing the presence of stone in the kidney.

Second Day—May 5th.

URETHRORECTAL FISTULA.

Dr. **James P. Tuttle** of New York read a paper on this subject.

After describing the various operations that have been resorted to in these cases, he gave a brief report of three cases of urethrorectal fistula coming under his care. In the first case the fistula opened into the rectum about half an inch above the external sphincter and was large enough to easily admit the end of the index finger. The floor of the urethra was absent to a considerable extent, and required to be rebuilt. There was considerable though not excessive connective-tissue deposit about the opening, and a stricture of the membranous urethra anterior to the fistulous opening. After several days of preparation and treatment to sterilize the urinary and intestinal secretions, he operated on August 30, 1896, as follows:

The sphincter was thoroughly incised and all the cicatricial tissue cut away with scissors, thus freshening the edges of the fistula at both ends. The intestinal wall was then dissected from its anterior attachments, up to a point three-quarters of an inch above the fistula and half an inch to each side. The stricture of the urethra was then operated on by perineal section, the incision being carried backward into the fistulous opening. A flap was then dissected from the soft tissues on each side of the urethra large enough to replace that portion of the floor which had been destroyed. These were sewed together with catgut sutures over a full-sized sound introduced through the meatus in order that the caliber of the canal might be accurately reestablished and no pocket left. The fistula being thus closed, the sound was withdrawn and the fresh perineal wound and anterior incision in the urethra left unsutured. The edges of the intestine were then sewed together with chromicized catgut and the rectum packed with iodoform gauze, a drainage tube having been introduced for the escape of gas. A soft, No. 12 catheter was introduced into the bladder through the meatus and fastened there. The perineal incision was loosely packed with absorbent gauze and dressed with an ordinary T-bandage. It seemed to cause no inconvenience, and was left in for eighteen days, the bladder and perineal wound being irrigated daily with Thiersch's solution. Convalescence was uneventful, the perineal wound healing in about six weeks. The patient left the hospital December 1, 1896, perfectly well.

PRIAPISM.

DR. R. W. TAYLOR of New York read a paper on this subject. He stated that the affection may be divided into the following classes: (1) Priapism observed in infants and children, induced by reflex action, in cases of long, tight, adherent prepuce, of stone in the bladder or prostatic urethra, and of worms in the rectum. (2) Priapism in adult subjects, symptomatic of stone in the bladder, stone in the prostatic urethra, stricture, cystitis, and observed during retention. In these cases the uneasy or painful sensation is felt in the glans penis, while the body of the organ usually is only moderately congested and sometimes curved downward or laterally. This condition disappears upon the removal of the cause. (3) Priapism symtomatic of gonorrhea, with perhaps involvement of the corpus spongiosum and downward curvature. This condition is painful and transitory, and may occur several times during the night. In cases of downward curvature of the penis due to inflammatory engorgement of the corpus spongiosum and spasm of the musculature of the urethra, the term "chordee" is applied. (4) Priapism due to the ingestion of cantharides, which is a form that is seldom or never seen now, since this drug is so rarely used in medicine. (5) Essential Priapism. This form, which was the only one considered by the author, may be divided into four varieties:

(*a*) Priapism caused by injury to the spinal cord (either high up or low down) and by blows or violence inflicted upon the perineum. (*b*) Priapism which is a symptom of cerebral or descending spinal-cord disease. (*c*) Priapism which occurs after alcoholic and sexual excesses; and (*d*) priapism which occurs in a person in ill health in whom it is difficult to obtain data as to local injury and causation, and in which cases there is now a tendency to look upon leucemia as the etiological factor.

In surveying the results of treatment of the cases of priapism already published, one is forced to the opinion that nothing like a routine method can be laid down. This much, however, can be stated with emphasis: Chloroform narcosis has failed in every case in which it has been used. Ice usually does more harm than good; electricity has no value, and even may be harmful, and leeches to the number of sixteen and forty have failed to produce any amelioration in the condition of the penis, and have been injurious in their depletory effects.

The speaker said that his own preference in dealing with these cases is to resort early to moderate and tentative incisions into the most turgid part, or into parts which are the seat of continuous pain, or into nodular masses, in all probability the result of traumatism. It is always good practice in priapism to use either the potassium salt alone or in combination with mercury, when a history of antecedent or present syphilis is elicited. A number of cases are on record in which the condition was relieved by potassium iodid. Bromid of potassium, chloral, belladonna, and morphin may be of benefit, especially during paroxysms. Hot baths, hot and cold spinal douches, sponging with hot water, spinal cauterization, anodyne poultices, and perhaps icebags may be found beneficial, but the latter must be used guardedly. Any ephemeral or systemic disorder should receive appropriate treatment.

CHRONIC CONTRACTION OF THE PROSTATIC FIBERS ENCIRCLING THE VESICAL NECK.

DR. EUGENE FULLER of New York read a paper with this title. He stated that the condition to which he referred as chronic contraction of the prostatic fibers encircling the vesicle neck represented a pathologic change, and was totally different from what the French writers have termed "neuralgia of the vesical neck" or "contraction of the vesical neck." The chronic contraction to which he referred, however, bears a relationship to the functional one in that it represents a pathologic state which may apparently result from functional contraction or spasm in cases where, owing to some settled disorder of the sexual apparatus, the rectum, the kidneys, or other organs, functional contraction of the vesical neck has existed as a prominent symptom for a long period. The contraction is permanent, rigid, and does not relax even under profound anesthesia. If a perineal incision is made in such a case, and the finger passed into the membranous urethra in an attempt to enter the bladder, the finger tip will find itself tightly engaged in a ring-like contraction in the deepest portion of the prostatic urethra, where under normal circumstances the canal should be wide, funnel-shape, and elastic, merging itself into the vesical cavity in such a manner that it is impossible to determine just where the urethra ends and the bladder begins. The presence of such a contraction, however, cannot be detected by means of a good-sized sound passed through the urethra. If the surgeon feels carefully with the finger-tip he will discover the urethra just in front of the circular contraction to be roomy and somewhat pouched. The mucous membrane of the entire portion of the deep urethra will ordinarily feel perfectly normal, and free from any evidences of previous inflammation. The condition is not associated with prostatic hypertrophy. After the contraction has been throughly ruptured or cut through, little evidence will be left to indicate the nature of the lesion which previously existed.

The clinical symptom prominent in such cases is an inability, either complete or partial, to void urine. This inability is of gradual development, and may at first be intermittent in character, but after a time it becomes permanent. Finally, all power to urinate naturally is lost and permanent recourse to the catheter is necessary.

A diagnosis of this condition has to be made largely from the clinical history of the case, together with an exclusion of other causes which may produce impediments to urination.

The only treatment for chronic contraction of the prostatic fibers encircling the vesical neck which, in the writer's experience, has been efficacious consists in thoroughly rupturing or cutting through these fibers. This treatment, in his hands, has been followed by complete disappearance of all subjective symptoms.

A NEW METHOD OF REMOVING POLYPOID GROWTHS FROM THE BLADDER.

Dr. George Chismore of San Francisco described this method, which was discovered by him accidentally. It consists of the introduction into the bladder of a litholapaxy catheter attached to an aspirator; by means of suction the growths are caught in the eye of the instrument, and by gentle traction and slight to and fro movements they are torn from their attachments, and drop into the reservoir of the wash-bottle. The speaker exhibited a number of vesical polypi removed by this method.

Dr. Charles L. Scudder of Boston reported

A CASE OF NEPHRECTOMY FOR CYSTIC ADENOMA IN A PREGNANT WOMAN.

The case was of interest (1) because bile pigment was found in a cyst of the kidney; (2) because the operation did not interfere with the completion of gestation, and (3) a second pregnancy since the operation was normal in every respect.

Third Day—May 6.

A POSSIBLE AID TO THE DISCOVERY OF THE TUBERCLE BACILLUS IN THE URINE.

Dr. John P. Bryson of St. Louis read a paper on this subject, in which he called attention to the fact that when tubercle bacilli are present in the urine, they are much more abundant in the residual than in the tidal urine. His experiments, which he detailed, showed a remarkable difference between the number of bacilli found in the tidal and in the residual urine.

THE RELATION OF OXALURIA AND URIC-ACID EXCESS TO GENITO-URINARY INFLAMMATIONS AND DISORDERS.

Dr. Bransford Lewis of St. Louis read a paper on this subject. He gave the following as his conclusions:

(1) Both oxalic and uric acid may appear in the urine, either in a physiologic or a pathologic manner. (2) When pathologic, they may exert certain injurious effects on the genito-urinary organs. (3) These effects may be either the inciting of disease where there has been previous health, or they may act by rendering more serious and resistant to ordinary methods of treatment other inflammations and disorders of those organs. (4) The uric-acid element is not always frankly evident as a casual or complicating factor in such cases. (5) And, when recognized, is neither more nor less easily controlled than where its disease-manifestations occur in other organs of the body. (6) When either the oxalic or uric-acid element is acting injuriously in the ways mentioned, systemic treatment (dietary, medicinal, and hygienic) is demanded, and may even take precedence over the local measures which are usually considered sufficient in such inflammations or disorders.

Dr. William K. Otis exhibited an instrument for photographing the interior of the living urinary bladder.

The following officers were elected for the ensuing year: President, J. William White of Philadelphia; vice-president, James Bell of Montreal; secretary and treasurer, Wm. K. Otis of New York.

AMERICAN ORTHOPEDIC ASSOCIATION.

Eleventh Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

(Continued from page 686.)

Second Day—May 5th.

Dr. Charles L. Scudder of Boston read a paper on

CONGENITAL DISLOCATION OF THE SHOULDER-JOINT.

He said that but very few cases of this condition have yet been reported, and he therefore felt justified in adding two to the list. The first was that of a girl, fifteen months old, who had been born after a hard labor. During the first week of life it was noticed that the right arm and hand were somewhat swollen. On examination, it was found that the right arm was rotated inward so that the right internal condyle looked backward, and that the head of the humerus was in the infraspinous fossa. The second case was that of a girl of three years, born without the aid of instruments, and after an easy labor. The right elbow in this case was held away from the side, and the forearm and humerus were slightly flexed. The humerus was rotated inward, as in the other case. The length of the right clavicle was 2⅞ inches, and of the left, 3⅛ inches. The humerus on the affected side was shorter, measured from the acromion to the condyle. The radius on the right side was half an inch shorter than on the left. In the first instance it was probable that the traumatism of labor played an important part, but this could not be said of the second case. From the measurements, it seemed highly probable that the distinctive feature between traumatic dislocation occurring at birth and true congenital dislocation of the shoulder was that in the latter there was always present a lack of development of the bones of the upper extremity.

A CASE OF ASYMMETRICAL DEVELOPMENT.

Dr. A. R. Shands of Washington, D. C., presented a boy illustrating this condition. This boy, now twelve years of age, was noticed to be unsymmetrical when he was only two years old. The circumference of the right calf at the middle is 15 and that of the left 9½ inches; the circumference of the right thigh is 18½ and of the left 13 inches. The length of the right and left legs are 28½ and 24½ inches respectively. Strangely enough, the larger thumb is on the small side. He is fairly intelligent, and has an excellent personal history.

SOME EFFECTS UPON THE LEG OF PRONATION OF THE FOOT.

Dr. John Dane of Boston presented a communication with this title. As a result of a careful study of the mechanics of the subject, he had arrived at the following conclusions: (1) In pronation of the foot the greater part of the foot remains stationary, and the leg rotates upon it. (2) In addition to the generally recognized motion of the malleoli inward and slightly downward, the normal outward rotation of the tibia and fibula is replaced by an exaggerated rotation inward. These changes together produce an alteration in the obliquity of the axis of flexion of the ankle-joint sufficient to destroy the mechanism of the ordinary method of supporting weight, and, as a consequence, flexion must be prevented and equilibrium wholly maintained by muscular force, thus quickly leading to fatigue. (4) This inverse rotation of the tibia interferes with the mechanism by which the knee should be locked. In the pronated foot, the knee must be kept in constant extension by muscular force, thus causing fatigue and extreme tenderness over the inner tuberosity of the tibia. (5) To compensate for this inverse rotation of the tibia and fibula, there is an exaggerated inward rotation of the fibula which, in its turn, overstretches the internal rotators of the hip, causing tenderness and pain in the calf and knee. (6) This explanation is wholly in accord with the clinical fact that when, by efficient mechanic apparatus, we have prevented pronation of the foot, we have relieved the pains of the calf, knee, and hip as well.

DR. R. W. LOVETT of Boston read a paper, entitled

FIFTY RESECTIONS IN HIP-JOINT DISEASE.

He formulated the indications for excision as follows: (1) When there is steady and persistent failure of the general health; (2) when the disease in the joint is progressive, as shown by much induration and discharging sinuses; (3) when severe pain and tenderness persist late in the disease; and (4) when there is formation of extensive sequestra in the joint.

DR. W. R. TOWNSEND of New York followed with a paper on

EXCISION OF THE HIP.

He said that from 1888 to 1896, 2295 patients with hip disease had applied for treatment at the New York Hospital for Ruptured and Crippled. Of this large number, 121 excisions had been performed on 119 patients. Abscesses, more or less septic, were present in 113 out of the 119 patients. This emphasized the necessity for opening, cleaning out, and draining all of these abscesses as soon as they became septic—indeed, many of the deaths were apparently the result of sepsis rather than of tuberculosis. In cases of extensive disease and severe sepsis, he believed that better results would follow amputation at the hip-joint, for although this would be undoubtedly followed by greater shock than excision, it would do away at once with all sepsis.

THE PRESIDENT attributed the rapidly growing sentiment in favor of avoiding excision to the influence of the conservative mechanic treatment. He still maintained that excision should only be done as a life-saving measure. In the acetabular cases it was not clear to him why amputation was preferable. The great value of the climatic treatment of these cases, he thought, would bear still further emphasis.

THE PROGNOSIS OF HIP DISEASE UNDER EFFICIENT TREATMENT.

DR. LEROY W. HUBBARD of New York read a paper with this title. He said that the prognosis, as regards life, was good, although the statistics from public institutions would seem to indicate that the mortality was as high as thirty per cent. The best statistics from private practice were those of Dr. C. Fayette Taylor and Dr. L. A. Sayre, and they showed the mortality to be approximately two per cent. The apparatus must be worn for two years in the average case coming under treatment at an early stage, and from three to six years in the neglected cases. According to Dr. Young, the disease was less manageable when developing after puberty, but this was not in accordance with his own experience. The painless form he had found to be the most common, and its course did not seem to be slower or less satisfactory. The shortening should not be over two inches. In making a prognosis, the family history and individual resistance should be given due weight, and it could be stated in a general way that the patient, in a given case, would probably recover with little or no deformity, and with some motion in the joint, and that the apparatus would have to be worn at least two years.

DR. E. G. BRACKETT of Boston read a paper on

GLUTEAL BURSITIS.

He said that in operating for the relief of this condition the incision should be made over the buttock, a little to the inner side of the outer border of the gluteus maximus muscle, and the fibers should be separated until the edge of the gluteus medius was reached. The tumor could then be easily exposed. It appeared as a well-defined, rounded swelling that suggested easy extirpation, but such was not the case. To remove the bursa usually required extensive dissection, and if too radical a removal were attempted there was danger of injuring the capsule of the joint. The wound should be packed, and would heal without leaving a sinus. For a short time after the operation, a high-soled shoe should be worn, and the motion of the limb restricted, but apparatus was not necessary. Bacteriologic examination in two cases had proved the tubercular nature of the bursitis. One of the cases reported developed hip-joint disease on the other side a year after the operation. In all the cases of gluteal bursitis limp was an early and persistent symptom, and occurred without remissions. Pain was not a prominent symptom, and was referred to the back of the leg and under the knee. It did not last long into the night. The chief limitation of motion was in extreme flexion, particularly flexion of the extended leg. Deep fluctuation could be detected in the upper part of the buttock. The ages of the patients varied from two to fourteen years.

THIRD DAY—MAY 6TH.

DR. JOEL E. GOLDTHWAIT of Boston read a paper, entitled

THE TREATMENT OF DEFORMITIES OF THE KNEE RESULTING FROM TUMOR ALBUS, WITH ESPECIAL REFERENCE TO THE CASES IN WHICH THE PATELLA HAS BECOME ADHERENT.

He said that very frequently in cases in which the patella is adherent to the end of the femur there will still be motion of 30° or 40°, but of course there will be loss of voluntary control in extension, as the anterior group of muscles are thrown out. The patella is situated almost always on the outer condyle of the femur, and when the tibia comes forward it strikes against this obstacle. It is possible to straighten the leg by tearing the posterior capsule, but of course this would leave the femur displaced backward. In one of the first cases operated upon by him the deformity had existed for a number of years, and the motion amounted to 35°. Failing to reduce the deformity with the genuclast, he opened the joint and removed the patella. It was then perfectly easy to bring the bones into place. Now, four years after the operation, the patient was able to go about. The convalescence was tedious, and the joint was very sensitive for two years. The motion which had been present before the operation had been lost. In subsequent cases, in order to shorten the period of convalescence, he had gone above the condyles, and done a regular Macewen osteotomy. He had then straightened the leg and corrected the knock-knee. The leg was put up a little extended. These cases had been extremely satisfactory, the convalescence short and the motion preserved. In rheumatoid cases there seemed to be nothing to do but perform excision of the joint.

DR. HENRY LING TAYLOR of New York then reported two cases of

GENERAL LAXITY OF THE LIGAMENTS WITH CONGENITAL HIP LUXATION.

General laxity of the ligaments, he said, might arise from abnormal traction, pressure of malpositions, or displacements, or pressure due to joint effusions.

DR. JOHN RIDLON presented a

SKIAGRAPH OF CONGENITAL DISLOCATION OF THE HIP.

The neck of the femur on the dislocated side *appeared* to be straighter than the normal neck. It was also evident that the leg, as a whole, was rotated outward so that the lesser trochanter was more prominent on that side than on the other.

DR. JOHN RIDLON read a paper, entitled

FOUR CASES OF RECENT FRACTURE OF THE NECK OF THE FEMUR.

He said that in 1892 he had published a paper embodying the results of treatment of twelve cases of fracture of the neck of the femur with the Thomas long hip-splint, and to these he would now add four more cases. He said that, briefly stated, his treatment consisted in reducing the deformity and securing approximation of the fragments, unless there was impaction present, and then the application of the Thomas long splint, with adhesive plasters on both sides. There were buckled to the ring, and "fixed traction" made to an amount represented by the weight of the splint. He was able in these cases to get the patient out of bed at the end of eight weeks, and to remove the splint a short time afterward. The uniform result was solid union and good use of the limb.

DR. R. H. SAYRE of New York reported a case of

COXA-VARA AS A MANIFESTATION OF LATE RICKETS.

The patient was a girl of sixteen in whom there was slight lateral curvature of the spine. The thighs crossed each other at the middle third. There was no muscular spasm and no tenderness, and the limbs were readily straightened by traction.

Following the discussion of the papers the regular business meeting was held and Dr. R. W. Lovett of Boston was elected President, and Dr. John Ridlon of Chicago, Secretary, of the Association for the ensuing year.

REVIEWS.

PREVENTATIVE MEDICINE; a brochure for the laity, being a practical treatise on the theory and the technic of the Prevention of Disease. By DR. CLARENCE RUTHERFORD HENDRICKSON, County Physician of Canadian County, Oklahoma; author of "Practical Lessons in English Grammar." Wichita, Kansas: 1896.

MISTAKES in diagnosis and inability to dispel disease are evidently not the only factors that the author of "Preventative" Medicine and "Practical Lessons in English Grammar"—two strongly contrasting titles—has to contend against. In his dedication he acknowledges the hardships of the early years of his eight of practice, and in his conclusion he lashes himself into a fury concerning patent remedies and quack doctors. The fences of Yukon, Oklahoma, must be as well covered with alluring advertisements and requests to "cure yourself" as the dead walls of New York.

Despite its innumerable errors, this little brochure contains much common sense, and its author is undoubtedly a studious, honest man. But why should the Oklahoma laity be afraid to clean its ears for fear of the *aspergillus*, and why, indeed, should it know so accurately about the gonococcus, the *bacillus typhosus*, the *bacillus mallei*, the *bacterium pneumoniæ crouposæ, et cetera?* We look by no means with favor upon semi-scientific medical brochures for the reading of the lay public and especially do we feel disinclined to see brochures on "preventative" medicine; so if we say that this one contains some common sense, it must be taken as very high praise.

TRAITE DE THERAPEUTIQUE ET DE MATIERE MEDICALE. Par VICTOR AUD' HOUI, Médecin de l' Hôtel Dieu de Paris. Paris: G. Steinheil, 1897.

THIS work of 1200 pages has been written for the needs of the student as well as for reference by the practicing physician. It is based upon a strict classification of drugs and upon the scientific determination—by experiment, mostly, of the action of medicinal agents. It contains an account of the older as well as of the more modern drugs, and describes in detail recently inaugurated therapeutic measures. Nosalogy, prophylaxis and pharmacology are considered in its pages, and following the preface, is a review of the bibliography of French works on therapeutics. The work is an exhaustive effort to place the modern view of therapeutics in all its phases on record, and is an excellent reference-book for everyone who is interested in the subject.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, JUNE 12, 1897. No. 24.

ORIGINAL ARTICLES.

VENEREAL DISEASE IN THE NAVY AND ITS PREVENTION.

BY R. PERCY CRANDALL, M.D.,
OF NORFOLK, VA.;
PASSED ASSISTANT SURGEON, U S. NAVY.

THE loss to the United States Government from venereal diseases in the naval survice for the year 1895, as shown in the report of the Surgeon-General of the Navy for that year, was equivalent to the total loss of the crew of such a vessel as the Castine or Machias for a period of six months. Incredible as this may seem, it is nevertheless true, and may be readily demonstrated in the above-mentioned report.

Owing to the admirable method of gathering statistics now followed by the Bureau of Medicine and Surgery, accurate results and data are readily obtainable. Previous to the report for 1895, it was impossible to estimate the exact number of cases of any one disease, as a case might appear first on the returns of a ship or station, and afterward on the returns of one or more hospitals, thus appearing as two or three distinct cases. Now, however, a case appears but once as an admission, and if sent to a hospital as a readmission, making the total admissions for the year represent the actual number of cases.

The "Report of the Surgeon-General of the Navy" for 1895 shows the total admissions for disease and injury to have been 10,625; of these 721 were venereal. Allowing thirty days for each case of venereal disease (which is very small), we have 22,351 sick days, or the loss of 61 men for one year, or 122 men for six months, about the strength of the Castine's crew.

It is impossible to ascertain the actual amount of venereal disease in the navy owing to the tendency to concealment; and again many cases are not entered on the returns when they are not incapacitated from duty. At several of the home stations the percentage of venereal diseases is very large. During the first four months of the present year, from January 1st to April 30th, there were under treatment at the United States Naval Hospital, Norfolk, Va., 150 cases of disease and injury, 50 cases, or 1 in 3 being venereal. In addition, some 12 or 15 cases developed while patients were under treatment for other affections, which do not show on the returns. Many of the cases were acquired at one brothel in the city of Norfolk from one woman, and yet, I found upon inquiry, that the police were powerless to interfere, and the woman still continues to infect the admirers who seek her favors. What better argument is needed than this in favor of police supervision and medical inspection of prostitutes.

We can never hope to stamp out prostitution, as long as the demand exists the supply will always be adequate, and prostitution is the chief source of all venereal diseases. Sanger says ("History of Prostitution") "it is a mere absurdity to assert that prostitution can ever be eradicated. Strenuous and well-directed efforts for this purpose have been made at different times. The whole power of the church where it possessed not merely a spiritual, but a secular arm, has been in vain directed against it. Nature defied the mandates of the clergy, and the threatened punishments of an after life were futile to deter men from seeking, and women from granting sinful pleasures in this world. Monarchs victorious in the field and unsurpassed in the council chamber have bent all their energies of will, and brought all the aids of power to crush it out, but before these vice has not quailed. The guilty women have been banished, scourged, branded, executed, held up to public opinion as immoral; their partners have been subjected to the same punishment; denuded of their civil rights; have seen their offenses visited upon their families; have been led to the stake, the gibbet, and the block, and still prostitution exists. The teachings of morality and virtue have been powerless here. In some cases they restrain individuals; upon the aggregate they are inoperative. The researches of science have been unheeded. They have traced the physical results of vice, and have foreshadowed its course. They have demonstrated that the suffering parents of this generation will bequeath to their posterity a heritage of ruined powers; that the malady which illicit pleasure communicates is destructive to the hopes of man; that the human frame is perceptibly and regularly depreciating by the operation of this poison, and have shown that even the desire for health and long life, one of the most powerful motives that ever influences a human being, has been of no avail to stem the torrent."

But while history has shown that prostitution cannot be crushed out, it has also shown that, by a proper system of regulation and supervision, its evils may be materially lessened, and the spread of venereal disease be reduced to a minimum.

Before considering further the regulation of prostitution as a means of prevention, I wish, first, to take up a few points that are particularly applicable to prevention in the naval service.

First, then, regarding enlistments.

Physical examinations for entry into the service should be more strict. Men frequently are passed who have had the initial lesion of syphilis, but at time of examination have not yet developed secondary symptoms, and frequently present no signs whatever by which the disease may be detected. If all men, after examination, were kept under observation for six or eight weeks before final enlistment, much loss of service would be saved the Government.

An elongated foreskin should be a positive bar to enlistment, unless circumcision is at once performed by the examining surgeon, thus decreasing the danger of acquiring venereal lesions. I have met with many cases, both in service and private practice, where men with elongated foreskins have contracted disease, and others, again, with retracted foreskins have cohabited with the same women, and passed unscathed. Treatment is rendered much more difficult, and the tendency to phimosis and phagedena is much increased where the foreskin constantly covers the glans.

Another important point which seems to have received but little attention is the periodical inspection of a ship's crew. This should be done at least once a fortnight, and, in addition, liberty parties should be thoroughly examined both before going on liberty and after returning. It is a firmly fixed belief among sailors that to get rid of a chronic discharge it must be given to some one else, and this they invariably do whenever the opportunity offers.

Dr. Kidder[1] relates that venereal disease became so prevalent in the Asiatic Squadron that a general order was issued in 1869 requiring the surgeon of each vessel to examine all liberty men, both on leaving and after returning to the ship. Unfortunately, the order exempted from examination all over thirty-five years of age, married men, and petty officers, and as the majority of the cases occurred among these classes, as shown by an examination of the medical journals, the order proved ineffectual. The Russian Government took a more effectual means about the same time. They obtained semiofficial possession of a deserted village called Hinassa, across the harbor from Nagasaki. "When any Russian ships arrived at the port they were accustomed to allow a certain number of women to migrate to this village where they were placed under the charge of a surgeon. The crew were then turned loose ashore only at this village, one watch at a time, during the stay of the ship. This characteristically direct proceeding proved eminently effectual, the amount of venereal disease on Russian ships being very small." (Kidder.)

In addition to the periodical inspection, the men should be instructed in sexual hygiene and the importance of ablution. When syphilized they should use individual mess gear, towels, etc., and be fully informed of the contagious nature of their disease.

Returning again to the most important preventive factor of all, the regulation of prostitution, it seems almost incredible that while thousands and thousands of dollars are spent annually to quarantine against yellow fever, cholera, smallpox, and other contagious diseases which occasionally occur, not a dollar is expended to control or prevent syphilis, which we have always with us. Nearly every civilized nation but our own has some form of regulation and supervision, by which the spread of venereal diseases is in a great measure checked and controlled.

Lecky says in his "History of European Morals": "In the eyes of most Continental writers, who have adverted to this subject, no other feature of English life appears so infamous as the fact that an epidemic which is one of the most dreadful now existing among mankind, which communicates itself from the guilty husband to the innocent wife, and even transmits its taint to the offspring, and which the experience of other nations conclusively proves may be vastly diminished, should be suffered to rage unchecked, because the legislature refuses to take official cognizance of its existence, or proper sanitary measures for its repression."

In the United States the experiment of regulation has been twice tried with the happiest results, but owing to misplaced sentiment and religious fanaticism, it was abandoned in both instances after a short trial. The first experiment was made at Nashville, and is described in the report of the Committee on the Prevention of Venereal Diseases presented at the eighth annual meeting of the American Public Health Association, of which Medical Director Gihon of the navy was chairman. Dr. Gihon says: "Colonel Fletcher of the Surgeon-General's Office of the U. S. Army, writes to your committee: 'In 1863, while I was on duty in Nashville, the question of the periodical examination of prostitutes, as a protection to the troops stationed at or passing through the city, was referred to another medical officer and myself. We drew up regulations for the purpose, and for nearly three years the women were examined, at first every two weeks, but subsequently every ten days.'

"I believe this was the first occasion of any systematic inspection of prostitutes attempted in the United States. Its results may be briefly stated thus:

---

[1] "Venereal Diseases in Japan."

"1. The amount of venereal disease was markedly lessened, so much so, that its occurrence came to be looked upon (absurdly, of course) as an imputation on the care of the examining surgeon. I have more than once known a company officer to complain that a man was off duty for disease caught of such a girl at such a time, and demanded that she be sent to the hospital.

"2. The women, who were at first rebellious, became quite reconciled to the system. I have known them to come to the hospital voluntarily, desiring to be examined for suspected disease.

"3. It was self-supporting, the fee paying the expenses of the hospital."

It may be mentioned here that the committee embodied their conclusions in the following resolutions:

"Resolved, that the American Public Health Association earnestly recommends the Municipal and State Boards of Health to urge upon the legislative bodies of this country the enactment of a law constituting it a criminal offense to knowingly communicate by any direct or indirect means a contagious disease, such as smallpox, scarlet fever, or venereal disease, and giving to said State Boards of Health, and the State and municipal officials under their control, the same power in the prevention, detection, suppression, and gratuitous treatment of venereal affections which they now possess in the case of smallpox and other contagious diseases."

The next attempt at legislation was made in St. Louis in 1872. The Missouri legislature enacted a law based on the system followed in Paris. Prostitutes were registered and subjected to medical examination at regular intervals, and when diseased sent to a hospital and retained until cured. Many of the evils of prostitution were abated, disease diminished, and the number of brothels and prostitutes decreased. Yet, in spite of all these beneficial results, a year had scarcely passed ere the clamor of the clergy and of the devotees of the innumerable religious organizations made itself heard and demanded the repeal of the law, which was eventually brought about and in a most dramatic way, as described by Sanger,[1] as follows: "A petition praying for the repeal of the obnoxious law, signed by more than 100,000 good people, was presented. The document was cumbersome. A wheelbarrow, decorated with white ribbons and accompanied by a group of innocent young girls, attired in spotless, white gowns, was brought into service, and on it the gigantic and emphatic protest against licensing of vice was wheeled up to the clerk's desk to be read. Courageous, indeed, would have been the country member who would have voted otherwise than he did." Counter petitions from the cities and the medical profession were in vain, the doctors of medicine were ignored, and the doctors of divinity won. And all this because the public at large and the clergy persist in regarding the regulation of prostitution as a moral problem, whereas it is a problem of sanitary science.

The great cry of the many associations for the prevention of licensed prostitution is that vice is made more attractive, that many timid ones who are now held back from gratifying their desires through fear of contracting disease would rush headlong to embrace the golden opportunity offered by the regulation system. How puerile this argument is, it is unnecessary to state. We know only too well, both as men and physicians, that the sexual instinct is so strongly implanted in man that he will risk Heaven itself for its gratification. This is especially true of our sailors, the majority of whom not only do not care about the risks they run, but in some instances are rather proud of their battle-scarred organs, and are ever ready to enter the lists for another tilt with Venus. The following will serve to illustrate this point: During my last cruise, an old boatswain's mate who had grown gray in the service presented himself at sick-call one morning with the announcement that he had *it* again; and he had—making, according to his own statement (which I had no reason to doubt), his eighteenth case of acute gonorrhea. In addition, I found that he had had nearly every other form of venereal disease, including syphilis. The undoubted pride which he took in his record, as he termed it, was a matter of much astonishment to me, although recent experience has shown me many such cases, even in private practice, where the risk of contracting disease was no check whatever to the gratification of the sexual appetite.

The enlisted men seek, as a rule, the lowest resorts, where disease always abounds more or less, not being admitted into the better class of houses, owing to their tendency to make trouble and leave behind some venereal memento. It is, then, doubly important that these houses of the lower class should be under police supervision and subject to medical inspection.

In February, 1876, a committee appointed by the New York Legislature to investigate the cause of the increase of crime made a report, from which I quote the following: "In the interest of the well-being, the decorum, the decency of society; in the interest of the peace and happiness of by far the greater number of people; in the interest of the preservation of the purity of the guardians of the public peace; in the interest of public health, and for the sake of thousands yet unborn, the committee earnestly urge upon the Legislature, as the only means of grappling with the social evil, the granting to the police the power of regulation, of localization, and medical visitation."

---

[1] "History of Prostitution."

It is needless to say that the carrying out of the resolution was violently opposed by that class of narrow-minded people who insist upon remaining blind to the presence of syphilis and the evils of unrestrained vice. "The gross ignorance of that class which busies itself about a speculative future, rather than an actual present, is an important cause of the non-recognition of the presence of syphilis. For this class, the idea of syphilis is inseparably connected with that of sexual commerce with an infected individual, and is considered as clear proof of chronic debauchery. Of a non-venereal origin, persons of this class have no suspicion. The initial lesion occurring elsewhere than upon the genitals is attributed to some other cause, and the disease is allowed to run its terrible course."[1]

"Suppress prostitution, and capricious lusts will overthrow society," said Saint Augustine[2] in the early Christian era, and the world's history has fully justified this opinion.

The state of New York City to-day is lamentable. The streets are overrun with prostitutes owing to the recent breaking up of the regular houses, and the smaller flats in the upper part of the city are thronged with them. This is especially dangerous, as they come in contact with the innocent and virtuous, the working girls, and the lower middle classes. Thus young girls are apt to be led aside from the paths of virtue by the glint and glitter of a fast life and this apparently easy and delightful mode of gaining a living. This condition of affairs is not found in Paris or Berlin where prostitution is under police supervision. One is not jostled at every turn in Paris by eager-eyed harlots as in London and New York. No better time than the present could be chosen to try the regulation system in New York City. The police force since its reconstruction would carry out strictly and honestly the provisions of such a system, prostitutes would cease to throng the thoroughfares, servants would no longer carry disease and sin into private families and young girls would be less liable to be corrupted.

Wherever suppression has been tried it has failed utterly. In Berlin in 1845 a royal edict was promulgated, under pressure, closing the brothels and discontinuing the registration of prostitutes. The result was disastrous, prostitutes filled the streets, theaters and dance-halls. Under the toleration system this had never happened, the girls being forbidden to appear in public places of amusement. Venereal disease multiplied so fast that the ordinary wards at the Charité were soon filled to overflowing and new wards had to be added to accommodate them, and finally syphilitics had to be sent to the Lazarette. Prostitution, which under police supervision had been confined to one quarter of the city now spread over the whole town and to the surrounding villages and even invaded private families through servants. Things reached such a frightful state eventually, that in 1851 the edict was repealed and police supervision restored and still exists. After a six-years' trial of the "crushing-out" system, it was admitted by the ministry to have been a complete failure. Nearly every civilized and semi-civilized nation has some form of supervision and regulation. In Belgium the system is very complete. In 1855 in an army of 30,000 men there were but 200 cases of syphilis. The Royal Academy of Belgium adopted the following resolutions in 1887:

1. The Belgium Royal Academy considers that the regulation of prostitution is necessary to restrain the development of venereal diseases and of syphilis.

2. Prostitution that advertises itself in the streets and public places, being the most potent cause in the propagation of venereal diseases and syphilis, should be interdicted.

3. Persons convicted of living by habitual prostitution should be inscribed and subjected to sanitary visits.

4. Registration and medical visits should only be authorized under safeguards that would, under each and every circumstance, protect the honor and dignity of the person.

5. From the exclusive standpoint of public health, the Academy declares that frequent and conveniently administered sanitary visits constitute the most efficacious means of arresting the propagation of venereal diseases and syphilis.

The Contagious Diseases Acts of 1864, 1866, and 1869 in England were productive of the most beneficial results in the army and navy. Before the acts went into effect, there were 108 cases of syphilis to the 1000 in the army. After the acts had been in force, the proportion of syphilis fell to 54 cases in the 1000 in 1874.

Much has been written both for and against these acts, but statistics show that syphilis decreased, brothels and prostitutes lessened in numbers, many of the evils of prostitution disappeared, and many young girls, warned by the police that they were under observation, gave up the life rather than be inscribed on the police register. Many reformed, owing to the facility with which they could be approached while in hospital by philanthropists and the clergy; others, again, married, settled down, and became respectable members of society.

[1] Fournier, *Gazette des Hôpitaux*, 1878.

[2] Tr. Ord. lib. ii, c. 12.

The *Lancet* of January 30th describes the startling condition of affairs of the army in India since the passage of the "Cantonments Act" abandoning the medical inspection of prostitutes visited by the soldiers. The increase in venereal diseases among the troops has been very great, 24,000 out of 73,000 suffering from special disease. One-half of the entire army are unfit for prolonged marching service. Medical inspection had proved invaluable in India, but the narrow-minded meddlers who are trying to lay up additional treasures in Heaven thought otherwise, and, under pressure, the "Cantonments Act" was passed. In spite of the fact that the Viceroy's council has urgently recommended the repeal of this mischievous act, it is still violently opposed in England.

At most of the foreign ports visited by our ships of war, regulation and supervision exist in some form. It is true that in some places the system is not strict enough, as in Spezzia, as shown in Surgeon Green's report of the recent cruise of the "Marblehead" in Mediterranean waters. While the ship was in Spezzia, during a stay of sixteen days, fifty per cent. of the crew contracted venereal disease. Dr. Green remarks, "that being a large garrison town, and the principal rendezvous of the Italian navy, one would think that a rigid inspection of prostitutes would be held; but, judging from the results as affecting our crew, hygienic laws in that direction must be very lax."

It is unnecessary to further multiply instances where the suppression of prostitution has failed and the regulation and supervision succeeded. The majority of medical men the world over are in favor of it, and even clergymen of the advanced type have recognized its advantages. The very able papers of Medical Director Gihon and J. William White should be consulted in this connection.

In conclusion, then, venereal diseases in the naval service would be reduced by:

1. Circumcision before or immediately after enlistment.
2. Applicants for the service being placed on probation after physical examination before final enlistment.
3. A periodical examination of the ship's crew, at least once a fortnight.
4. The examination of all liberty parties both before and after returning from liberty.
5. The use of individual mess gear, washing utensils, etc., by syphilitics on board ships and in hospitals.
6. The regulation of prostitution by a system of registration, police supervision, and medical inspection.

THE INCREASING FREQUENCY OF DIABETES MELLITUS.

By H. A. HARE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE.

THE medical profession, in the face of conflicting theories as to the etiology and pathology of diabetes mellitus, and recognizing the futility of treatment in many cases of the disease, has nevertheless reached certain conclusions in regard to it which seem to become more certain as additional evidence is adduced. The first of these is that the gravity of the affection is in direct proportion to the youth of the patient; the second, that after fifty years of age, and particularly in stout persons, its gravity is greatly modified, and the third, that it is a disease affecting the male sex far more frequently than the female. Usually this proportion is from three to two to six to two, but Cantani, in 1004 cases, found 83.37 per cent. males and 16.63 per cent. females. This proportion is nullified in childhood when females are equally or more commonly affected than males. Finally, diabetes mellitus is a disease which is extraordinarily on the increase nearly all over the world, although there are exceptional localities to which this statement does not apply.

The relative death-rate from diabetes is well known owing to the careful reports now provided so universally by boards of health and census returns, and it is chiefly from this source that we learn of the increase in mortality and probable morbility just named.

As an illustration of this fact I may call attention to three series of statistics which particularly emphasize this increase. Thus "Purdy on Diabetes" points out that the United States census of 1880 gave a death-rate of 72 per 100,000 for 1860; 98 per 100,000 for 1870, and 170 per 100,000 for 1880. The results of the census of 1890 are 191 per 100,000. In other words, from 1850 to 1880 (thirty years) the increase of mortality from diabetes was 150 per cent. A certain proportion of this increase must, however, be placed to the credit of improved diagnostic methods, coupled with the fact that in the earlier reports a greater number of patients with diabetes were reported as dying from carbuncles, galloping consumption, and other diseases which destroy this class of patients. It is worth noticing that the greatest increase in the frequency of diabetes was in the ten years from 1860 to 1870, or during the war decade, during which time the entire nation was under great nervous strain and, according to Purdy, became more free livers so far as wines are concerned. It is interesting to note that the number of diabetics in this decade in England was not proportionately great. The increase, however, is by no means limited to the United States. This fact is shown by the statements of Saundby[1] who points out that from 1884 to 1893 17,794 persons were registered as dying from diabetes in England and Wales, whereas, according to Roberts, in the decade of 1851–1860 the death-rate was only 4546. Again, Saundby shows that even allowing for the increase of population the increase in mortality is over 70 per cent. or 90 per cent. if this is not allowed.

Finally, so far as the statistics of others are concerned, I may cite those of Fowler[2] in which he shows the mortality from diabetes in New York to have risen from 42 in 1878 to 105 in 1887 estimating the population as averaging 1,400,000. These statistics, as compared with the population, are not as accurate as if the proportion to actual population in each year had been given. In Philadelphia from 1870 to 1880 (eleven years) the deaths were 206.

So much then for the general statistics, which might be greatly increased in number. I will pass on to a consideration of the relative frequency of the disease among the living, in connection with which I hope to be able to adduce some few statistics myself. In this line very little is to be found in medical literature, in which almost all statistics deal with the relative death-rate.

Senator[3] states that Romberg, out of 10,000 patients in the Berlin Polyclinic, found only three diabetics, and again from 1872 to 1874 there were in 16,550 patients six diabetics. In Griefswald, out of 4640 patients there were three diabetics according to Ziemssen and Marmé. In Wurzburg, out of 4460 patients there were seven diabetics. At Jena, however, according to Ruicholdt, there were 13 cases in 5153 patients, and this was nearly twenty-five years ago.

In this connection the statistics I have been able to gain from the reports of a number of English hospitals and from the Jefferson Medical College Hospital are of interest particularly when they are compared with the statement made by Osler in regard to the Johns Hopkins Hospital in Baltimore where out of 35,000 cases only 10 cases of diabetes occurred. As a large number of these patients were probably negroes, and the disease is rare in this race, the great difference between his statistics and my own may be explained.

In the Jefferson Medical College Hospital, which treats a moderately well-to-do class for hospital patients, the following facts are obtainable: From September 1, 1890, to October 1, 1891 (thirteen months) there were 5 cases in 2485 in the out-patient department, and from October 1, 1891, to May 16, 1892 (seven months) there were 7 cases in 3036. In 1893 there were in the wards 193 cases, of which 2 were diabetics, and in the dispensary service 3727 cases, of which 8 were diabetics, or 10 cases in 3920 patients. In 1894 there were none in the wards, but in 3484 cases in the dispensary there were 8 cases. In 1895 there were 4 cases in the wards out of 263 cases, one in the private wards out of 237 cases, and 3 cases in the out-patient department out of 3392, or 8 cases in 3892 patients. In 1896 there were 2 cases in 323 in the medical wards and 10 cases out of 3184 in the out-patient medical department. We find, therefore, that out of 24,051 cases there were 50 cases of diabetes mellitus.

I have also collected the following statistics from three English hospitals:

Hospital.	Year.	Patients.	Diabetics.	Males.	Females.
St. Bartholomew's..	1860......	5724	9	0	0
	1861......	5585	8	0	0
	1862......	5389	6	0	0
	1863......	5462	8	0	0
	1864......	5543	6	0	0
	1865......	3519	7	0	0
	1866......	3065	11	0	0
	1867......	1938	10	0	0
	1868......	No record.			
	1869......	2343	6	4	2
		38,568	71	4	2

Up to 1867 the records do not separate medical and surgical cases. The column under "Patients" thus includes both classes. Hereafter it includes only medical cases. The year 1869 is the first in which males and females are separated.

Hospital.	Year.	Patients.	Diabetics.	Males.	Females.
St. Bartholomew's..	1870......	2317	9	6	3
	1871......	2366	11	8	3
	1872......	2204	15	10	5
	1873......	2382	19	13	6
	1874......	2496	14	5	9
	1875......	2354	8	5	3
	1876......	2596	16	11	5
	1877......	2290	20	13	7
	1878......	2418	12	11	1
	1879......	2560	15	9	6
		23,983	139	91	48
	1880......	2640	16	9	7
	1881......	2647	21	18	3
	1882......	2949	16	9	7
	1883......	2806	14	10	4
	1884......	3109	20	12	8
	1885......	2713	21	14	7
	1886......	2416	26	17	9
	1887......	2543	20	13	7
	1888......	2579	21	13	8
	1889......	2296	22	12	10
		26,698	197	127	70

	1890	2023	10	7	3
		19,327	81	71	28
	1891	1990	11	7	4
	1892	2065	15	11	4
	1893	2037	7	4	3
	1894	1910	10	7	3

This hospital shows a much smaller increase in diabetes than St. Bartholomew's. In the decade of 1861–1870 the proportion was 47 cases, while from 1881 to 1890 it was 81 in 19,327. All the studies refer to ward cases not to out-patient departments. It seems evident, therefore, that diabetes mellitus is far more prevalent in England and America than it was some years since, and that it is far more common than some of the text-books would lead us to believe. The proportion at this time in hospital practice is about 1 in 540 cases, and could private statistics be obtained it would probably be far higher in the upper classes. In England it is apparently far higher than here.

INFECTION BY THE URETHRAL SOUND.

By G. FRANK LYDSTON, M.D.,
OF CHICAGO;
PROFESSOR OF GENITO-URINARY SURGERY AND SYPHILOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF ILLINOIS.

THERE are excellent practical reasons for the consideration of infection by means of the urethral sound independently of catheter infection. So much has recently been added to our knowledge of the latter mode of infection that there are at the present time certain well-established principles governing the use of the catheter, and the results of infection are fairly well understood. Contrasting the use of the two instruments, the differences are: (1) the conditions under which they are introduced; (2) the size of the instruments used; (3) the diseases for which instruments are systematically employed.

The catheter is an instrument designed essentially for the diagnosis and treatment of diseases of the bladder. It is not, so to speak, from a surgical standpoint at least, a urethral instrument. The sound, on the other hand, while occasionally used for vesical exploration, is inferior to certain other instruments for that purpose, and its field of usefulness is chiefly in the diagnosis and treatment of urethral disease. The catheters employed in diseases of the bladder, for the purpose of evacuating the urine and irrigating the viscus are not usually large, and their introduction may be attended by little or no traumatism of the urethra and structures about the neck of the bladder. Such traumatisms as may be inflicted are due, as a rule, not to the large size of the instrument, but to the pathologic conditions encountered on the way to the bladder. In the case of the urethral sound, the instrument being used principally for the purpose of dilatation, it is obvious that it may be necessary to resort to quite large-sized instruments on account of the conditions present. It is a self-evident proposition that the composition of the instrument very largely governs the degree of traumatism inflicted during its introduction. As the soft catheter is so frequently used nowadays, the danger of traumatism has been greatly minimized. Sounds, however, and, within certain limits, bougies, are composed of relatively dense materials, and it is possible with very slight force to inflict considerable injury upon the urethra and vesical neck.

The catheter is usually used for the purpose of evacuating the bladder, either for remedial purposes, or with the object of procuring fluids for examination, and oftentimes for the purpose of irrigating the viscus. In many cases the instrument is introduced only once, or at rare intervals; whereas, the conditions indicating the passage of sounds are likely to demand dilatation at more or less frequent intervals over a long period of time. The class of cases which demands the systematic introduction of the catheter and withdrawal of the urine, as is true of certain cases of atony of the bladder and enlarged prostate, must, of course, be taken into consideration. In these cases, however, there is often very little to be guarded against save personal or catheter uncleanliness.

I believe it is the experience of every surgeon to have occur in his practice cases of infection due to the introduction of sounds in the treatment of urethral disease, and especially in stricture. Increased opportunities for observation have convinced me that trauma is a very much more important factor than most surgeons are aware. It is therefore best for the surgeon to understand plainly that his instrument is passing through and over an infected area every time he passes a sound. It is quite generally understood that there is great danger of the transference by the sound from the anterior to the posterior urethra and bladder of infectious materials during the passage of the instrument. This occurs in the larger proportion of instances in which the sound is introduced in the ordinary manner. Infection, however, does not occur in by far the larger proportion of cases even when sounds of improper form are introduced. This relative immunity of the deeper structures and bladder to infection is due to the fact that little or no harm is done to the mucous membrane. Should damage be produced at any point in the urethra, vesical neck, or bladder proper, an atrium for infection is at once afforded and pathologic phenomena, consequent upon such infection, are very likely to arise. In looking at the ordinary sounds sold in the instrument shops, I am really surprised that so few cases, comparatively, of infection by means of the sound occur. The ordinary urethral sound is some inches longer than is absolutely necessary, and when introduced in the manner advised in various text-books, must necessarily invade parts far beyond the site of the disease for which they are used. Let the surgeon take, for example, one of the monstrous sounds sold in all of our instrument shops and introduce it into the urethra in a case of stricture at the bulbo-membranous junction; let the sound be swept downward toward the feet, as recommended in the diagrams in the text-books — which diagrams I regret to say I have presented in my own work on stricture—and the point of the sound will be found to be three or four inches beyond the point which it is desired to dilate. It will project several inches into the bladder, which is entirely unnecessary, and will in all probability impinge on the anterior vesical wall. It will surely do so if the bladder is empty, or only moderately distended. This projection of the instrument far beyond the site of the disease which is under treatment is an element of danger that must be obvious to every practical surgeon who will give the matter any consideration. This danger may be obviated by using sounds with a very short shaft. The ordinary urethral sound is supplied with a conical point. There is often great temptation to wedge such an instrument through the point of obstruction in the urethra, thus producing a traumatism, which might be avoided. There is a temptation with this form of faulty sound to the introduction of sounds several sizes larger than should be introduced. I have obviated this fault in the construction of sounds by devising a set, the points of which conform as nearly as possible to the shape of the distal extremity of the metallic exploring bulb. Such sounds are abruptly stopped by obstructions through which one would sorely be tempted to wedge a sound with the ordinary conical point.

There are numerous conditions that may arise as a consequence of sound infection. The most important of these are: (1) periurethral folliculitis and phlegmon; (2) plastic inflammation of the corpus spongiosum, with resultant cordee; (3) exacerbation of a pre-existing urethritis; (4) Cowperitis; (5) posterior urethral inflammation, which almost inevitably extends to the glandular tissues of the prostate; (6) true inflammation of the vesical neck; (7) acute or chronic follicular prostatitis; (8) prostatic and periprostatic abscess; (9) seminal vesiculitis; (10) true cystitis; (11) urethral chill and fever of various grades of severity; (12) orchitis and epididymitis; (13) gonorrheal rheumatism of varying forms.

Spasmodic and congestive stricture of varying degrees of severity may occur as one of the phenomena following sound infection. A point worthy of consideration is the fact that the results of sound infection may occur at a point remote from the traumatism and infection inflicted by the sound. Prostatic abscesses undoubtedly occur in many instances as a result of prostatic and periprostatic inflammation due to infection of the tissues through the medium of the lymphatics, the atrium of infection being in some portion of the urethra quite remote from the point at which the serious results develop.

Having considered the results of sound infection, it becomes necessary to consider prophylaxis. Much can be accomplished by rendering the urine aseptic by the administration of various internal remedies. The best urinary antiseptic for internal administration is, in my opinon, oil of eucalyptus. Boric acid, or boric acid combined with salol, are only moderately efficient by comparison. By asepticizing the urine as nearly as possible, the absorption of infectious materials by the tissues at the site of such traumatisms as passing a sound may have inflicted may possibly be avoided.

An essential point for consideration is the condition of the genito-urinary tract at the time it is proposed to pass the sound. If the existing inflammation is at all acute, no instruments whatever should be passed when it is possible to avoid it.

I believe the form of sound is the most important point for consideration. The shaft should be several inches shorter than the ordinary urethral sound, and its point should be distinctly conical, corresponding as nearly as possible to the distal extremity of a metallic urethral exploring bulb. The sound should be perfectly aseptic, and there is no better method of making it so than by allowing a stream of hot water to flow upon it. In lubricating the sound some unirritating aseptic or antiseptic material should be used, vaselin or albolene with the bichlorid of mercury of a strength of about one in two thousand is as good a lubricant as I know of. Rancid oils and soap should be avoided. In systematic dilatation of stricture the contraction should not be dilated more than one size at a sitting, and great care should be taken not to introduce a sound of a size sufficient to put the stricture tightly on the stretch. In addition to the danger of traumatic infection, such a faulty method of introduction of the sound in the treatment of stricture is likely to transform a previously tractable stricture into the resilient and irritable type.

A CONTRIBUTION TO THE KNOWLEDGE OF THE ANATOMY OF THE LEVATOR ANI MUSCLE.

By WILLIAM W. BROWNING, M.D.,
OF BROOKLYN;
PROFESSOR OF ANATOMY IN THE LONG ISLAND COLLEGE HOSPITAL.

WHILE differences of opinion may reasonably exist as to the function of a muscle, it would seem that investigators should agree upon the disposition of its fibers. An examination of the literature bearing upon the levator ani muscle, however, reveals the most astonishing differences in its description. These differences have reference more particularly to the course and insertion of its fibers. Concerning its origin there is practical agreement. Gynecologists and obstetricians, as a class, consider the muscle in the female as a very important structure, while many maintain that it is the principal support of the pelvic contents and an active factor in parturition. For this reason writers upon the anatomy of the female pelvis have given it especial consideration. The ideas which prevail of its form and function have been gained, therefore, from this class of investigators, rather than from works on descriptive anatomy.

Since there is practically no dispute as to the origin of the levator the following is quoted from Testut: "The muscle originates (1) in front from the posterior surface of the body of the pubic bones on each side of the symphysis; (2) behind from the internal aspect of the ischiatic spine, and (3) in the interval included between these two points from a sort of fibrous arch which extends from one of the above points to the other and which may be regarded as a thickening, on its margin, of the obturator fascia."

The beautifully illustrated work of Savage on the female pelvic organs may be considered classic, and the following, quoted from Symington[1] expresses his views: "Savage divides each levator into two portions, which he names the pubococcygeus and the obturatorcoccygeus." I believe that these two portions differ not only in their arrangement but also in their function. The pubococcygeus arises from the posterior surface of the pubes and the posterior layer of the triangular ligament. Its fibers pass backward on the side of the lower part of the vagina, and on the side of the anal canal, to the last two pieces of the coccyx. A few of its innermost fibers turn inward, in the perineal body, in front of the internal sphincter of the anus. Behind the anus, and in front of the coccyx, there is a partial blending of fibers of opposite sides in the middle line.

"The pubococcygei act as sphincters of the lower part of the vagina and of the anal canal, but they cannot compress either the upper part of the vagina or the rectum. They also draw upward and forward the perineal body and coccyx."

"The obturatorcoccygeus consists of those fibers of the levator ani which arise from the pelvic fascia between the pubes and the ischial spine. Its fibers run backward and inward to the coccyx. These fibers have no direct action upon any of the pelvic viscera. They constitute a thin layer of muscle, which, in addition to raising the coccyx, can elevate the pelvic floor a little, after it has been depressed."

Although the nomenclature of Savage has not been adopted, his description has been extensively accepted as authoritative, and his illustrations have been very generally copied.

The description of the levator ani, as given by H. Von Luschka, has also been accepted with great confidence by many gynecologists and obstetricians. It differs materially from that of Savage, and is well set forth by Dr. Robert L. Dickinson of Brooklyn, N. Y., in the September number of the *American Journal of Obstetrics* for 1889. From this article, which is profusely illustrated, we would gather that *no* fibers of the muscle reach the vaginal wall; that a few, more deeply seated than the rest, and coming from the pubic band, turn into the perineal body; that most of the fibers of pubic origin unite behind the rectum with their fellows from the opposite side *without the intervention of tendon* and that *none* reach the coccyx; that the fibers from the ischial spine are inserted into the coccyx; that those of the fascial origin curve downward and backward, with varying obliquity, *and with concavity forward*, to be inserted into a raphe reaching from the rectum to the coccyx. The muscles of the two sides thus together form, in the main, a sort of funnel-shaped sheet slung about the rectum posteriorly, and "hugging the concavity of its end curve."

---

[1] *Edinburgh Medical Journal*, March, 1889.

We note that Dr. Dickinson misrepresents Savage in stating that he named the fibers of the levator as arising from the spine of the ischium, "ischiococcygeus." The "ischiococcygeus" of Savage is the *coccygeus* of other authors.

Recently I have been investigating the levator with no little care. Dissections of the muscle in the male and in the female, both of man and of the lower animals, have been made, and the findings carefully recorded. Though as yet not prepared to enter into minute detail, I have progressed far enough to unhesitatingly declare that the description of Savage is much more nearly correct than that of Luschka, and that the illustrations of Dickinson create an entirely erroneous impression.

While the remarks which follow have reference to the levator ani as it appears in the female, I desire to call attention to the fact that the muscle is as well, if not better, developed in the male.

The levator ani muscle may very properly be divided into three portions. This division has reference both to the origin and to the insertion of its fibers. The so-called pubococcygeus of Savage arises from the intrapelvic surface of the body of the pubes and the posterior or superior layer of the triangular ligament. This latter fascia blends with the obturator fascia along the descending pubic ramus, thus rendering the origin of this portion of the muscle more extensive than usually described. It will be seen also to be on a plane, superficial to and intersecting that of the portion of the muscle posterior to it. The fibers arising as above described soon gather to form a band distinctly separable from the rest of the muscle, and about one-half inch in width and one-eighth inch thick. It takes a course nearly horizontally backward to the anus. At its insertion it is bilamilar. The superficial fibers are continued into the external sphincter ani muscle. Of the deep fibers a few turn forward and are lost in the perineal body. I have been unable to trace them to the median line. By far the greater number take a backward course. Posterior to the rectum they come in close contact with their fellows from the opposite side, but are *not* continuous with them "without the intervention of tendon." Some terminate in the recto-coccygeal raphe, but many reach the coccyx. I have been unable to verify the statement of some authors that fibers from the pubic band terminate in the rectal wall or even in a fascia closely connected therewith. The pubic band as it sweeps by the vagina is separated therefrom by an interval of one-quarter inch, but a few stray fibers from its lowermost origin cross it and terminate in the vaginal wall.

The fibers of the levator ani which arise from the ischial spine from a distinct bundle separable also from those of fascial origin. It takes a transverse course and is, for the most part, inserted into the fourth coccygeal segment. A few superficial fibers, however, turn forward and are inserted into the recto-coccygeal raphe. This bundle might very properly have been denominated the ischiococcygeus muscle, though it was to the coccygeus that Savage gave that name.

The intermediate portion of the levator ani is thin and membranous. It consists of a number of fascicles which arise from a fascia weakly attached to the "white line." Their direction is downward, backward, and inward toward the rectum and the recto-coccygeal raphe. I have not been able to trace any of these fibers to the rectal wall, but find that when they reach the side of the rectum and approach the raphe, all turn sharply backward and run nearly parallel to the middle line. Some reach the coccyx; others become aponeurotic before doing so.

It has been the good fortune of the author to have examined the pelvic floor of a young female over which the head of a fetus of eight-months' development had passed within the preceding forty-eight hours. In this case there was no evidence of the stretching of the fibers of the lavator, such as is described and illustrated by Dr. Dickinson in the article referred to. On the contrary, the muscle was compact, firm, and well developed, and demonstrated in a most marked manner the points to which attention has been called in this paper.

The levator ani muscle is lined by the thin anal fasci, which is closely adherent to it. On the other hand, it can be easily dissected from the strong rectovesical fascia which lies superior to it and which sends processes to the bladder, the vagina, and the rectum, and between them. I am disposed, therefore, to disagree with those authors who describe this latter structure as part of the sheath of the muscle.

There can be no doubt but that the muscle, from its insertion into the perineal body, the external sphincter ani, the postrectal raphe, and the coccyx, pulls upward and forward the postvaginal structures of the pelvic floor. A very noticeable result also of traction upon the pubic band is to evert the anus.

Those who have conducted investigations upon the lower animals will have noticed the proportionately greater development of the levator ani in those possessed of a tail, and that its function in such animals is almost entirely to act upon that structure.

While it was not my intention in presenting the foregoing considerations to venture outside the field of anatomy, I am tempted to suggest as objections to the claim made that the levator ani is the principal support for the pelvic contents of woman :

1. That in the human subject it belongs to the class of rudimentary muscles.

2. That the weakness of its origin as well as the direction and the insertion of its fibers is inconsistent with such design.

3. That it is unphysiologic for a muscle to furnish a continuous support.

4. That the rectovesical fascia is in itself sufficient, when intact, to afford the required support.

5. That the muscle is no better developed in the female (in whom support is most required) than in the male.

CLINICAL MEMORANDUM.

PRIMARY TUBERCULOSIS OF THE BREAST OCCURRING DURING PREGNANCY.[1]

By EDWARD P. DAVIS, M.D.,
OF PHILADELPHIA;
PROFESSOR OF OBSTETRICS AND DISEASES OF INFANCY IN THE PHILADELPHIA POLYCLINIC; CLINICAL PROFESSOR OF OBSTETRICS IN THE JEFFERSON MEDICAL COLLEGE, AND MEDICAL DIRECTOR OF THE JEFFERSON MATERNITY; VISITING OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

PRIMARY tuberculosis of the breast is one of the uncommon conditions, the description of which is found in the literature of general surgery. Gynecologic and obstetric writings afford but scanty mention of this complication of pregnancy and the puerperal state. In the *Annals of Surgery* for January, 1897, Powers reports a case, and has been able to find but thirty-seven others in the literature of surgery. With the exception of the monograph by Piscacek of Vienna, I recall no account of these cases in the writings on gynecology or obstetrics.[2] In the present instance, the condition was diagnosticated during pregnancy, and the puerperal period was treated in accordance with this complication. The diagnosis was confirmed at operation, subsequently to the patient's recovery from childbirth.

The patient, B. W., aged seventeen years, applied for admission to the Jefferson Maternity, November 18, 1896, being pregnant seven and a half months. Her family history was negative; her own health had been fairly good before pregnancy occurred. Regarding her antecedents, nothing positive could be learned. She had intended to have an abortion produced, but was persuaded to allow the pregnancy to go to term. She was admitted to the Maternity on November 28th, although her labor was not expected until the latter part of January or the first of February.

On admission, she complained of pain in the right breast, aggravated by moving the arm and shoulder, and sufficiently severe to cause loss of sleep at times. On examination, her pelvis was found to be normal; the fetus occupied the first position, the vertex presenting. Its movements were vigorous, and its heart-sound was plainly recognized. The mother's urine was normal, and she complained only of the pain in the breast. She was excessively pale and somewhat anemic. The breast was found to be swollen, firm, and indurated in its outer and lower quadrant ; the gland was freely movable upon the pectoral muscle, the induration being confined exclusively to the parenchyma of the breast. No evidence of fluctuation could be obtained, nor could the axillary lymphatics be detected. There was no evidence of heat in the affected breast, the skin was slightly discolored, and the pain was described as cutting rather than throbbing. The patient stated that she first noticed the swelling a month before admission, when she was about six-months pregnant. The pressure of her clothing aggravated her suffering. No considerable amount of fluid could be pressed from either breast. Enough was obtained from the affected side for microscopic examination, when abundant colostrum corpuscles were detected. The patient denied having suffered violence of any sort. The breast was thoroughly cleansed with an antiseptic solution, a breast-binder applied, and the patient put to bed, with the hope that the induration might lesson. A week's rest in bed was followed by a slight diminution in the size of the breast, but no essential change occurred.

On December 24th, a month after admission, the secretion from the breast was thoroughly stained and examined by Dr. David Bevan, and tubercle bacilli detected. Examination of the other portions of the patient's body revealed no evidence of tuberculous infection. The case was seen in consultation by Dr. W. W. Keen, and the question of immediate operation was discussed. As no abscess could be detected, and as the patient could ill afford the loss of blood which must accompany an amputation of the breast during pregnancy, it was determined to wait until her child had been born, and she had completed her puerperal period, before resorting to a radical procedure. Should fluctuation occur at any time, it was decided to immediately incise the breast and evacuate its contents. The patient was accordingly given appropriate tonics, and the breast-bandage continued. There was a steady increase in the size of the breast during her pregnancy, and under active exertion, pain became decided. Her temperature was repeatedly taken, but found to be normal. Her general condition remained good.

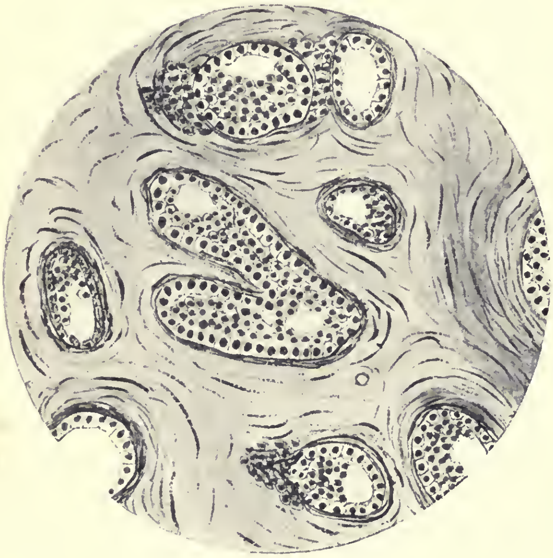
---

[1] Read at the Twenty-second Annual Meeting of the American Gynecological Society, Washington, D. C., May 5, 1897.

[2] The following are the few surgical papers available on this subject:
Bender, *Centralblatt für Chirurgie*, 1891, p. 819.
Mandray, *British Med. Jour.*, December 19, 1891, p. 197.
Roux, Geneva, 1891.
Recinche, *Centralblatt für Chirurgie*, 1895, p. 484.
Gaudier and Pépaire, *Rev. de Chirurgie*, September, 1895, p. 768.

On February 2d her confinement occurred, the child being delivered with forceps as her strength proved unequal to the completion of labor. The child was fairly nourished, considering the mother's condition. Its placenta was examined by Dr. Bevan to determine the presence of tubercle bacilli, but none could be detected. The mother made an uninterrupted convalescence from labor. She was not allowed to nurse her child, the infant being artificially fed, and the breasts being tightly bandaged. On March 19th, Dr. Keen, with my assistance, amputated the right breast in its entirety. The fascia in front of the pectoral muscle was resected with the glands. The axillary fascia was incised, but no enlarged glands were found in the axilla. But little loss of blood accompanied the operation, and although the patient suffered shock, she rallied quickly from it.

FIG. 1.



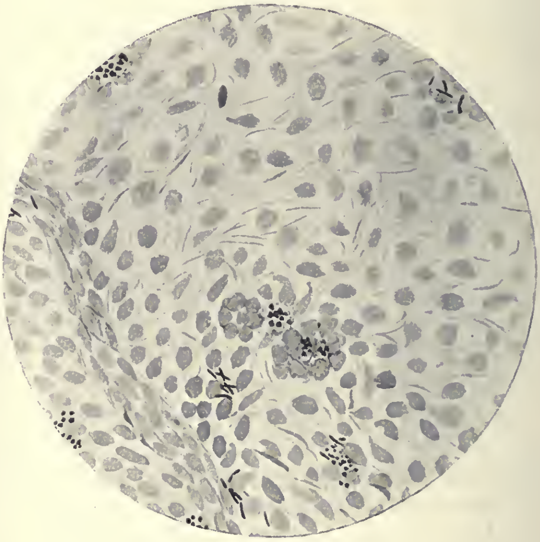
Adenomatous Tissue in Affected Breast.

Gross examination of the breast showed the presence of small multiple abscesses in the various acini. A hard mass in the upper portion contained a considerable amount of pus in its center. In the lower portion a tumor, resembling an adenoma, was found. Stab-cultures were made from the breast, and the gland was given to Dr. Beven for examination; his report is as follows:

"Inoculations of tubes of agar-agar at a temperature of 90° F., gave growths of micrococcus pyogenes albus after three-days' time. Microscopic examination of pus scraped from the wall of the abscess showed micrococci and tubercle bacilli in abundance. A section was made of the breast through the outer margin, microscopic examination of which showed the structure of an adenoma; slight hemorrhage had occurred into the stroma of the gland, and its epithelial cells were proliferating and beginning to invade the stroma. This tissue closely resembled a beginning carcinoma. A second section was taken from the center of the gland, showing hemorrhage more marked than in the preceding. A third section from the margin of the tumor showed increased growth of epithelial cells, as shown in Fig. 1. A fourth section comprised the wall of the abscess where were found marked proliferation of connective-tissue cells, and embryonic tissue in the form of leucocytes. Tubercle bacilli and micrococci were found in abundance; this is illustrated in Fig. 2."

A review of the pathology of this case shows that the patient had an adenoma of the breast, which became infected with tubercle, and under this infection broke down readily in the formation of pus. The fact that the other breast remained without evidence of disease may be owing to the absence of an adenoma on that side, and the better resistance of the tissues to the tuberculous invasion. She made an uninterrupted recovery from the operation, and repeated examination of the other breast failed to reveal evidences of disease. The child did well for several weeks, but perished April 14th from marasmus. A *post-mortem* examination of its body failed to find evidence of tuberculous infection.

FIG. 2.



Tubercle Bacilli in Connective Tissue of Breast.

In the absence of systemic infection, it is naturally interesting to determine the manner in which the breast could have become diseased. Although the patient denied all information, inquiry from others makes it more than probable that the breast became infected through contact with the mouth of a tuberculous individual. It is hard to account for the condition on any other ground. It is interesting to observe that the infection remained entirely limited to the mammary gland. It caused no reaction which manifested itself in fever or general disturbance. Had a diagnosis not been made, however, and had the child been allowed to nurse, its infection must have followed. During the last few years in my out-patient service at the Philadelphia Polyclinic, two cases have been detected by my assistant, Dr. Coles, in which mothers having tuberculous breasts were nursing tuberculous infants. I have seen a similar condition in the wards of the General Hospital in Vienna.

So far as diagnosis is concerned, this is impossible in the early stages without careful microscopic examination. In anemic young women, a first pregnancy is sometimes accompanied by considerable turgescence of the breasts, which may be increased to induration by the rubbing and pressure of clothing. The upper border of a corset tightly worn may greatly aggravate this condition. Soon after the admission of this patient, a married women entered the Maternity, suffering from a tumor of the breast, following a kick or blow; she was at the same period of pregnancy. In her case, a simple induration was diagnosticated because the microscopic study of the contents of the breast revealed no other condition. She subsequently made a perfect recovery, and nursed her child. Sarcoma and scirrhus growths may also occur in pregnant patients, and may increase rapidly during gestation; they generally produce, however, greater injury to the general health.

Through the courtesy of Dr. W. W. Keen, I am enabled to add the following note of the only case of primary tuberculosis of the breast which he has seen with the exception of my own: The patient, Miss C., aged twenty-five years, was first seen November 6, 1889. The late Dr. Agnew had diagnosticated a sarcoma of the left breast. Upon examination, the patient was found to be cachectic and said she had felt tired and miserable for a year. On August 12th, while in Europe, she observed a lump at the axillary border of the left breast; it felt as though bruised, although there was no history of an injury. She had sharp pain in the entire breast. The tumor grew rapidly until it not only involved the outer border of the breast, but extended into the axilla as far as the posterior border and up to the vessels. The patient suffered also from tingling in the arm. The nipple was not involved. Examination of the blood and urine was negative. The clinical diagnosis by Dr. Keen and Dr. Agnew was that of sarcoma. At operation, the tumor at the border of the breast was found to consist of two tuberculous abscesses which had invaded not only the axilla, but the breast also. The entire gland was removed. The wall of both abscesses was completely dissected out and one gland, the size of a pigeon's egg, and a number of smaller ones, were removed, some of them from just beneath the clavicle. They were very adherent to the walls of the vessels, especially to the veins, and were removed with difficulty. Dr. Coplin found that not only were the abscesses tuberculous, but that the breast itself was involved extensively in tuberculous degeneration. The patient made a complete and permanent recovery.

MEDICAL PROGRESS.

Ultimate Results of Hysterectomy for Carcinoma.—BOUILLY has been investigating the results of hysterectomy for carcinoma of the uterus, and he publishes in the *Bulletin General de Thérapeutique*, March 15, 1897, the rather discouraging results of his researches. Of forty-six patients in whom recurrence had taken place, in two instances there was no evidence of the disease for three years after operation, while in one recurrence was not detected for four and a half years. These three patients were aged forty-seven, sixty, and thirty-eight years respectively, and the operation was performed in the early stages of the disease. In no less than forty-one instances recurrence took place in one year or less, and in nearly every one of these death occurred a few months later. In women under thirty-five, recurrence seems almost certain.

In the light of these statistics, the question may well be raised whether hysterectomy for cancer is justifiable, a question which Bouilly answers in the affirmative, not only because in many cases the symptoms make life without surgical relief almost unbearable, but also because these results, discouraging as they are, are not worse than those obtained by operation upon cancers in other portions of the body. In the period between the vaginal hysterectomy and recurrence the patient believes herself cured, and for this time she possesses all the results of a radical cure. There is no hemorrhage, no pain, no disturbance of function, and no visible evidence of mutilation to annoy her, as is so often the case in operation for cancer of the breast, etc. These are the ideal results of surgical interference, and, even if they last only a few months, the time gained is very grateful to the patient.

Traumatic Origin of Renal Calculi.—WEBER (*Münch. Med. Wochen.*, March 23, 1897) narrates the case of a man, aged nineteen, who fell from a ladder, striking upon his back and sustaining an injury to his head. There followed a complete paralysis of the left leg and a partial paralysis of both arms. There was also complete paralysis of the bladder and rectum, which continued for nearly six months, and then gradually disappeared. The paralysis of arm and leg was also recovered from. The diagnosis was made of hemorrhage into the spinal canal, with compression of the cord, which was relieved by gradual absorption of the blood clot. Two years after the accident the patient noticed that urination was painful and that he passed gravel. Cystitis was marked. Later, attacks of renal colic set in, and the patient died about five and one-half years after the accident. Both kidneys were the seat of suppurative pyelonephritis with dilated pelves, which contained numerous large calculi.

Weber was of the opinion that the fall in this case produced laceration of both kidneys, and that the extravasations of blood, acting as foreign bodies, produced inflammation and deposits of urinary salts.

Spontaneous Disappearance of Cataract.—KOENIG mentions an instance (*Le Progres Méd.*, May 1, 1897) of spontaneous disappearance of cataracts in both eyes in a woman of seventy years suffering also from diabetes, and passing at times as much as six ounces of sugar *per diem*. Suitable glasses were ordered and the patient was put upon a diabetic diet. Two years later she was seen again, and was found to be still suffering from the diabetes, though in a less degree. The diet was still rigidly ahhered to. The eyes were absolutely free from the slightest opacity.

Fracture of the Clavicle Treated by Incision and Suture.—Spencer (*Amer. Journ. of the Med. Sciences*, April, 1897) reports two cases of fracture of the clavicle treated by incision and suture of the fragments. In both cases the subclavius muscle was found lying between the fragments, and in one of them there was in addition a loose piece of bone. The ends of the bone were sutured together by fine catgut, the stitches being passed through the periosteum only. The incision in the skin was closed with fine silkworm-gut sutures, and the arm was dressed in the Velpeau position with a light plaster-of-Paris bandage. The result in both of these cases was excellent, and the deformity was insignificant.

Regeneration of Bone from Periosteum.—In *Medicine*, March, 1897, Thompson records the case of a boy, aged fourteen, who received at close range a charge of shot in the upper third of the right arm. The wound was dressed by a physician, several detached pieces of bone being removed, and an attempt was made to wire the ends of the bone together. Ten days later, when Thompson first saw the case, the wound was suppurating, the soft parts were edematous, and the general condition of the patient was bad. Measurements showed that four inches of the humerus was wanting, and the periosteum was found in shreds and strips. The wound was cleansed and treated daily with antiseptic irrigations, and the patient recovered in less than four weeks, there being solid bony union and scarcely any shortening. The defect in the skin had been partially made good by skin-grafting. The strength and motion of the right arm was completely restored.

Radical Cure of Hernia.—In the March number of the *Annals of Surgery*, Coley reports 360 operations for the radical cure of hernia, with one death, due to double pneumonia in a child with bronchitis. The method employed in most cases was that advocated by Bassini, although in some instances the canal was sutured without transplantation of the cord. Of 325 cases of inguinal hernia, only 6 were known to have relapsed; 26 cases were lost sight of. The remaining patients were in good condition. Over 200 of these had remained sound for more than a year. As most cases which recur do so within six months after operation, the outlook for permanent recovery in these cases is very satisfactory.

Means of Recognizing Minute Perforations of the Tympanic Membrane.—Valsalva's maneuver (which consists in forcible expiration while the mouth and nose are tightly closed) fails to detect very small perforations of the tympanic membrane. These can be recognized (*The Medical Week*, April 30, 1897) by either of two methods, one of which consists in introducing a Siegle's pneumatic speculum so as to rarify the air in the external auditory meatus. If there is no perforation the tympanic membrane is seen through the glass plate in the speculum to bulge outward. If there is the least opening in the membrane it remains immobile. The other method consists in connecting the auditory meatus of the patient by a rubber tube to one opening of a double-mouthed vial filled with tobacco smoke. The patient then executes Valsalva's maneuver and if there is the smallest opening smoke will issue from the vial.

Injections of Osmic Acid in Neuralgia.—Franck (*Centralblatt f. Inn. Med.*, April 10, 1897) recommends the use of osmic acid in obstinate cases of neuralgia, a remedy which has proved invaluable in his hands, as well as in those of several others quoted by him, especially in the worst cases. The injections produce a sharp pain which lasts but a few moments, apparently because the nerve fibers are destroyed by the action of the acid. No visible necrosis or ulceration follows its use. A one-per-cent. solution is employed and must come in direct contact with the nerve in order to relieve the pain. This explains the fact that in some cases success was not obtained until several injections distributed over a period of from one to six weeks had been employed. For facial neuralgia it is advisable to begin with minute doses.

THERAPEUTIC NOTES.

For Pruritus of Jaundice.—

℞	Menthol		gr. xxiv
	Alcohol Ether	aa	ʒ iv.

M. Sig. For external use, apply as a spray to itching regions.

For Vaginismus.—Lataud advises irrigation with potassium chlorate and tincture of opium, aa 200 parts; tar water, 200 parts; a tablespoonful to a quart of water at bedtime, after which the following bougie should be inserted:

℞	Cocain hydrochlorate	gr. iv
	Ext. belladonna	gr. ii
	Strontium bromid	gr. iv
	Oil of theobroma	ʒ ii.

For Gonorrheal Cystitis in Women.—

℞	Ammonium benzoate	ʒ iii
	Tr. hyoscyamus	ʒ iss
	Ext. buchu, q.s. ad.	℥ ii.

M. Sig. A teaspoonful in water four times daily.

For Constipation.—

℞	Aloin		gr. iv
	Ext. cascara sagrada		gr. viii
	Ext. belladonna Ext. nux vomica	aa	gr. iii.
	Ft. Cap. No. viii.		

M. Sig. One capsule at night as required.—*Montgomery.*

For Eczematous Blepharitis.—

℞	Hydrogen dioxid	℥ i
	Vaselin	ʒ v
	Lanolin	ʒ iiss.

M. Sig. Apply to inflamed lids.—*Wood.*

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

VENEREAL DISEASE IN INDIA.

UNDER the title of "The Moral and Physical Ruin of the British Army in India, Due to a Defiance of Nature's Laws," an editorial writer in the *Indian Medical Record* has some very hard things to say about the Contagious Diseases Acts, and also about the present system, or lack of system, in attending to the health of the soldier from a sexual point of view. The former was bad, and the latter is worse in his opinion. The *Indian Record* advocates the remedy that was suggested in the NEWS of last week, *viz.*, marriage, or as the writer laconically states it, "a home and a wife for every man."

"It is our conviction then," says this writer in closing, "that the enforced celibacy of the greater portion of our European soldiery is an economic mistake. . . . In the Annual Report of the Sanitary Commissioner with the Government of India for 1895, these significant facts are recorded: (1) Among the European troops of India there were 522 admissions from venereal diseases for every 1000 men, while among the native troops there were only 31. (2) Those native troops that are serving in regions farthest away from their homes, appear to be the most affected by venereal disease.

"What an oft-repeated object lesson is illustrated by these facts. Will not the Government of India and of Great Britain learn the lesson here taught and thus redeem the British nation from physical and moral decay and also at the same time remove a blot that tarnishes its escutcheon before the whole civilized world? Away from their homes our soldiers suffer. Plainly God's law is marriage, and the cure is in the hands of our rulers. They prefer concubinage and prostitution for our British soldiers, and the result is destruction and death. What monumental folly to proscribe marriage for the British soldiery in India A reversion to the old Honorable East India Company's tactics of having life-time service in India for the British soldier, with *a home and a wife for every man*, is the only plan that will ever prevent the moral, physical, and financial ruin and wreckage of human life, that is being perpetrated every day in India by the blind folly of the British Indian Government in regard to our European fellow-subjects of the Queen in India. The whole Christian community of this country should raise its voice in united protest against this vile and inhuman violation of Nature's laws, and plead for a recognition of that justice and liberty that would give our European soldier a HOME AND A WIFE in India."

In connection with this subject attention is called to the exceedingly interesting and instructive article of Passed Assistant Surgeon Crandall on the control of venereal diseases in the United States Navy, which appears in this issue of the NEWS. This will be followed by others of a similar character, with the hope of shedding sufficient light upon this complicated subject to be of service in the evolution of some rational system of controlling venereal disease.

THEORY OF THE MOVEMENT OF THE NEURON.

THE theory of the movement of the neuron, as it is called, has begun to attract general attention, and ought to be known to every physician who pretends to keep in touch with medical advance.

It was in 1890 that a German (Rabl-Ruckard) first advanced the idea that the essential nerve-cells, the neurons, were not fixed, but had ameboid movements; but this idea attracted little comment. Later, Lépine and Duval of France and Dercum of this country came independently to the same conclusion, and the more the theory is discussed, the wider becomes its support. Whether it is finally proven to be true or false, it explains far better than any previous theory many physiologic and pathologic nervous phenomena.

Take a case of hysteric paralysis of a single limb —complete—scarcely to be recognized from a gross lesion, but which may in a few hours completely disappear. No one longer holds the idea that hysteria is simulation. How does the theory of the neuron explain the phenomena? Very simply. The cortical cells in the motor area have processes extending toward the surface—dendrites—and a protoplasmic process extending downward through the white matter of the brain, the internal capsule, the crus, the pons, the medulla, and into the spinal cord, where it terminates in a brush-like extremity—the end tuft. Here it has a certain relation with the motor cells in the anterior horn of the cord—probably one of contact, though that is not definitely known, According to the theory of movement of the neuron, in hysterical paralysis the nerve-processes retract and this contact is broken. If under the influence of hypnotic suggestion or otherwise the paralysis disappears, that is simply saying that the abnormal contraction of the nerve-process is, for the time being, relieved; contact once more takes place and motion is possible.

Take a physiologic process—sleep. This has often been explained as a cerebral anemia, notwithstanding the fact that true cerebral anemia, for instance after hemorrhage, is marked not by sleep, but by wakefulness. Evidently, if the neurons are functionally active, their dendritic processes must be in contact; without this, consciousness is impossible. When the nerve-cells are exhausted by fatigue, there is every reason to believe that their volume shrinks, and it is therefore more and more difficult for them to remain in contact. When relaxation comes, the processes retract and unconciousness, *i.e.*, sleep supervenes. It is extremely probable that ether and chloroform circulating in the blood cause the neurons to retract their processes and so produce unconsciousness.

The theory is indeed fascinating, and it grows more so as the special functions of cortical areas are investigated. Thus, if a song is sung, the sequence of sound-vibrations impinges upon the peripheral auditory neurons, that is, the nerve-cells of the spiral ganglion of the cochlea. It produces in these neurons a change which affects the relations which their neuraxons (that is, their centripetal processes) bear to the nerve-cells of the auditory nuclei of the medulla, and, secondarily, to the neurons in the auditory area of the cortex. It is probable that the effect produced upon the latter is to cause them to retract, extend, or otherwise move their processes, and thus bring about a change in the relations which the various neurons of the auditory area of the cortex bear to one another. It is evident that the same sequence of sounds must always produce the same combinations in the cortical area.

The act of conception of a familiar sound or series of sounds will consist in the reformation among the neurons of the same combinations as were produced when the sounds actually impinged on the ear.

Memory, also, in accordance with this theory, depends not upon fixed cerebral structure, but upon the combinations of the neurons formed from time to time being the same as, or similar to, those previously formed. For example, when a familiar tune is heard the old combinations among the neurons in the auditory cortical center are reformed and the tune is "remembered." But the excitation does not stop here but travels through the general cortex of the brain setting in motion a series of combinations among the neurons along the oldest and best-traveled lines; and visual memories as well as auditory ones are produced, and besides hearing the familiar song, there is a recollection of the singer, or of a parlor, or of an operatic performance, and so forth.

To follow out all the possibilities of this theory is beyond the scope of this article, whose purpose is only to call attention to it, and to make it clear by brief illustrations. A thoroughly comprehensive article on the subject—one which is free from unnecessary technicalities—is written by Dercum and published in the *Philadelphia Polyclinic*, April 3 and 10, 1897.

ECHOES AND NEWS.

Modern River Dwellers.—It is calculated that 21,000 people sleep nightly aboard the steamers on the rive Thames.

Mount Sinai's Training School.—Twenty-seven nurses were graduated June 2d from the Mount Sinai Training

School for Nurses, at Sixty-seventh street and Lexington avenue, New York.

Assistant Surgeon-General of New York.—Nathan Sturges Jervis was commissioned at the Adjutant-General's office, Albany, June 4th, as Lieutenant-Colonel and Assistant Surgeon-General of the State National Guard.

Criminal Proclivities Inherited.—Alfred Fouillée declares in the *Revue des Deux Mondes* that in the case of eighty per cent. of young French criminals, the moral condition on the side of the parents is deplorable. Vice, debauchery, and drunkenness in the parents become criminality in the child.

A Woman Resident Physician.—Dr. Mary O'Malley who graduated last month from the Medical Department of Niagara University has been appointed one of the residents at the Buffalo Hospital of the Sisters of Charity. Dr. O'Malley is the first woman to receive such an appointment in Buffalo.

Schlatter Reported Dead.—A despatch from El Paso, Texas, announces that Schlatter, the divine healer who had such a remarkable though brief career in Denver, Col., in 1895, has been found dead in the mountains near Casa Grande, Mexico. He had been fasting, and apparently had starved to death.

The Most Honorable Position of the Medical Profession of England.—The *London Medical Press* says that the Blue Ribbon of the surgical profession in England is undoubtedly the presidency of the Royal College of Surgeons, and there are few who are successful in obtaining a seat in the Council who do not aspire to this honor.

Lord Lister and the British Army.—Now that Lord Lister has interested himself in the discussion before the House of Lords on the health of the British Army in India in reference to venereal disease, the British medical periodicals are encouraged to believe that some reasonable provisions for inspection and control will be enacted.

New York Delegates to the Charities Conference.—The State Board of Charities has appointed Drs. Enoch V. Stoddard of Rochester, Stephen Smith of New York city, Charles S. Hoyt of Canandaigua, and Mr. R. W. Hibbard of New York city, Secretary of the Board of Charities, to represent the State at the National Conference of Charities and Correction Organizations to be held in Toronto on July 7th.

The University Bellevue Hospital Medical College.—It is credibly reported that the combination entered into by the University Medical School and the Bellevue Hospital Medical College has been annulled. The Utopian dreams of an ideal medical institution which were inspired by the announcement of this coalition have vanished. The perfection of the future plans and aspirations of each institution will now be awaited with no little interest.

Foreign Doctors in Italy.—In Italy foreign doctors are permitted to practice among foreigners only, unless they possess an Italian diploma, or are expressly called in consultation for special cases. As the competition in the medical profession is becoming more active the Italian doctors are agitating the question of restricting the practice of foreigners to those who have obtained an Italian diploma. The resident English and American doctors have taken alarm from this and are taking steps to prevent the restriction.

Meeting of the American Electro-Therapeutic Association.—The next meeting of this Society will take place on Tuesday, Wednesday, and Thursday, September 21, 22, and 23, 1897, at Harrisburg, Pa. The Harrisburg Academy of Medicine has offered the use of their building, and the Dauphin County Medical Society has appointed a special committee of arrangements to act for the Association. There is a promise of a fine display of electrical instruments and their practical operation. MAX EINHORN, M.D., secretary, No. 20 East Sixty-third street, New York.

Liberal Gifts to the Flushing Hospital.—Less than three months ago the Board of Managers of the Flushing Hospital Association issued an appeal to the public asking for contributions with which to pay the operating expenses of the institution. Cash contributions and subscriptions were plentiful. A few weeks later a millionaire resident of Whitestone sent his check for $10,000 to the hospital management, and last Thursday another Whitestone resident authorized a hospital director to have the hospital buildings thoroughly overhauled and repaired at his expense. Now the hospital has funds that will last at least three years. Happy Flushing Hospital!

Recreation Piers in New York.—The first of the recreation piers has been finished. It is at the foot of East Third street, and will be opened to the public on June 19th. The pier is 300 feet long, 60 feet wide, and cost $54,000. The Dock Board is at work on three more recreation piers—at the foot of Twenty-four, and One Hundred and Twelfth streets, East River, and at the foot of Christopher street, North River. One or two of them will be ready for use this summer. Such provision for the relief of mothers and children during the hot days of summer is a happy idea and a wise expenditure of funds. The cool refreshing air which circulates along the river front with the incoming tide can thus be enjoyed by thousands to whom a day excursion on one of the charity barges is impossible on account of household duties.

London Sewage.—The sewage of the largest city in the world, London, is handled by two main pumping stations on each side of the Thames, with machinery of an aggregate of 3000 horse-power, capable of pumping some five hundred million gallons per day, and a like number of storm-water pumping stations, capable of pumping directly into the river 150,000,000 gallons per day—the latter being used for preventing flooding in the lower parts of the metropolis when a heavy fall of rain occurred at or about the time of high water, when the storm outlets were closed by the rising tide. The outfall works for the purification of the sewage, the dry-weather flow of this exceeding 200,000,000 gallons per day, consists of settling tanks and their accessories for the chemical treatment of the sewage, and the means for removing the sludge produced to the ocean. The tanks at Barking are rated at 20,000,000 gallons, and those at Crossness at 31,000,000, the sludge, amounting to more than 2,000,000 tons, being discharged into the open sea at a distance of about fifty miles from the works by a fleet of steamers.

Dangerous Inks.—The *London Lancet* calls attention to the serious injuries which sometimes result from an apparently trifling scratch or puncture made with the pen. The chemical constituents of the ink which is introduced by the pen into the wound are not capable of producing septicemia, but microscopic examination proves that the ill-effects are due to the liability of ink to contain pathogenic bacteria. Dr. Marpmann of Leipsic has recently published the results of the microscopic examination of sixty-seven samples of ink used in schools. Most of them were made with gall-nuts, and contained saprophytes, bacteria, and micrococci. Nigrosin ink, taken from a freshly opened bottle, was found to contain both saprophytes and bacteria. Red and blue ink also yielded numerous bacteria. In two instances Dr. Marpmann succeeded in cultivating from Nigrosin ink a bacillus which proved fatal to mice within four days. This ink had stood in an open bottle for three months, and the inference to be drawn from the inquiry is that ink used in schools should always be kept covered when not in use. The practice of moistening the pen with the tongue is likewise a dangerous one.

Obituary.—Dr. Henry E. Turner, probably the oldest practicing physician in Rhode Island, having recently observed his sixtieth anniversary as a doctor, died in Newport June 2d, after a brief illness. He was born in Greenwich, R. I., eighty-one years ago, and early went to Newport, where he at once identified himself with local affairs. He was for many years city physician of Newport.—Dr. Francis L. Dickinson, one of the oldest and best-known physicians of Rockville, Conn., died in New Haven June 2d. Dr. Dickinson was born in Chatham, Conn., in 1817, and was graduated from the Yale Medical School in 1840. He served several terms in the State Legislature, and was State Senator in 1877 and 1878.—Dr. Asa F. Pattee, a practicing physician for thirty-one years, died at Boston May 31st. He was a native of New Hampshire, and was descended from a long line of physicians, extending back to William Pattee, who was physician to Oliver Cromwell and Charles II. He received the degree of doctor of medicine from Dartmouth College, and in 1859 began practicing in Amesbury, Mass. In 1883 he was elected Professor of Materia Medica and Therapeutics at the College of Physicians and Surgeons, Boston. He was a member of the Massachusetts Medical Society, the American Medical Association, and for several years President of the Boston Therapeutical Society. He was an honorary member of the Botanical Society of Italy, and in 1887 received the degree of M.A. from Dartmouth College. His contributions to medical literature were many.

A Medical Student Seventy-five Years Old.—Recently we had occasion to call attention to the advanced age of a medical student in Bodwin, Maine. His experiences are surpassed by a Russian, the following account of whom is taken from the *Lancet:* "A student named Borysik has just passed the final examination at Warsaw University qualifying him to practice as a doctor of medicine in Russia. Borysik was born in 1822, and was educated at Suvalk Higher Grade School with a view to becoming a medical man. After matriculation lack of funds prevented him from at once proceeding to the university, and he was compelled to work as a tutor for twenty years in order to save enough money to enable him to continue his studies. At the end of that time he presented himself at the Warsaw Medical Academy and passed the entrance examination with distinction. Before he could begin his studies the Polish rebellion of 1863 broke out, and Borysik, who was now forty-one years of age, threw himself into the movement with all the enthusiasm of a youthful revolutionist. The revolt was suppressed, and Borysik was exiled to Siberia, where for thirty-two years he underwent hard labor in the silver mines. In 1895 he received a free pardon and returned to Warsaw. In spite of his age and the hardships he had endured, Borysik had lost none of his enthusiasm for medical work, and took up his studies where he had left off in 1863. After a two-years' course this remarkable man has now, at the age of seventy-five years, passed the final medical examination with honors, and will begin to practice in Warsaw."

The Antivivisectionists.—Again we are pained by the receipt of letters from different towns and signed with different names, but written on the same subject and paper, and apparently on the same typewriter. Both are based this time on the vigorous remarks of Dr. W. J. Robinson about the vivisectionists, which were printed in this column a few days ago. One comes from Sing Sing, and bears the signature of "Sydney Lawrence"; the other nominally originated in Yonkers, and appended to it is the name "A. Morris." Both of these epistles are couched in courteous and good-tempered language, as their predecessors have been, if memory serves. Long and sorrowful experience with this particular sort of literature has produced the conviction that there are not in the whole country two antivivisectionists who can discuss the one question that interests them with an approach to common decency of speech. Mr. Lawrence-Morris can do that, and more, and we are almost tempted to publish his letters. If he will only read a few of the very accessible authorities on recent progress in medicine and surgery, the Lawrence part of him will not have to ask what the vivisectors have accomplished, and the Morris part will no longer regard the demonstration of anatomic facts before classes of infants as the one ambition of scientific investigators. At present Mr. Lawrence-Morris's letters are of insufficient interest to justify publication in any except journals devoted to the study of morbid and arrested mental development. His case is not hopeless, however, and if he would not try to live in two towns at once he might easily find time to acquire information enough to make his communications welcome and printable.—New York *Times*, June 7th.

CORRESPONDENCE.

OUR VIENNA LETTER.

[From our Special Correspondent.]

THE AUSTRIAN GOVERNMENT PLAGUE COMMISSION IN INDIA—FIRST REPORTS OF YERSIN'S SERUM FOR PLAGUE NOT CONFIRMED—INSUFFICIENCY OF THE ILEOCECAL VALVE AND ITS CAUSES — PROFESSOR NEUSSER ON THE DIAGNOSIS OF CARCINOMA OF THE STOMACH—RECENT DECORATIONS FOR AUSTRIAN PHYSICIANS.

VIENNA, May 15, 1897.

AN unofficial preliminary report of the work of the Commission sent to India by the Austrian Government to investigate the plague has just been published. So far forty-one autopsies have been made, and owing to rigid antiseptic and hygienic precautions and extreme care in the handling of material the members have escaped infection. They are more fortunate in this respect than their colleagues of the German Government Commission. One of the latter, Dr. Stricker, became infected through an autopsy wound and had a genuine attack of the plague. It fortunately proved to be but a slight attack, and he recovered after an illness of but a few days.

It would be interesting to know what the natives think of these meddlesome foreigners who come from so far, thrusting their heads into the lion's jaws to study the dreaded plague close to the bedside, and yet not satisfied, with utter disregard of the danger, pursue their studies even on the bodies of the dead, Such action must accomplish much in reassuring the common people and keeping them from giving way to the senseless panic which so often does much to spread disease in a time of epidemics.

The Commissioners do not seem to be as sanguine of the efficacy of Yersin's serum as are their colleagues from France and do not seem to have observed such unfailing favorable results from its use. Whether this is to be set down as a little "Chauvinism," German-speaking scientists being characteristically slow in admitting that anything good emanates from France, or whether, as is usually the case in things medical, the first reports were a bit high-colored by the sanguine confidence of pioneers remains to be seen. Meantime the world cannot help but admire the thorough spirit of self-forgetfulness in the cause of science which prompts men to calmly put themselves in positions of ever imminent danger in the hope of learning enough of the much-dreaded plague to be able to stay its ravages.

At a recent meeting of the Vienna Medical Club, Dr. Herz demonstrated certain points in the pathologic anatomy of the ileocecal valve. The subject is not a new one, but most of the peculiarities found *post-mortem* in this valve have been considered to have no clinical significance. Dr. Herz divides the conditions he has observed into relative and complete insufficiency of the valve, with a further stage of chronic thickening, induration, and permanent pouting of the edges which he names ectropion. He has found that such insufficiencies occur especially in heart cases and in chronic dysentery. The sclerotic ectropion occurs after long continuance of these two conditions and in chronic alcoholism. He demonstrates the relative and complete insufficiency of the valve by subjecting it to certain pressures of water. A perfect valve will resist water pressure enough to cause rupture of the intestines. Relative insufficiency is, of course, a purely artificial distinction applied when the valve will tolerate only a certain amount of pressure—for him about twenty feet. The whole subject is usually slighted by clinicians and even by pathologists and yet is concerned with such important organs that the calling of attention to it cannot fail to be of interest.

Professor Neusser began his clinics for the summer semester with a series of three clinics on carcinoma of the stomach. As the great point of interest in the cases is the early and positive diagnosis of the condition, and as Neusser is looked upon as one of the greatest of diagnosticians some notes on the subject may prove interesting.

The usual points of physical diagnosis are made clearer by putting the patient into a warm bath when much resistence to palpation, owing to tense unyielding abdominal muscles, is encountered. It is also a routine practice to determine the position of the tumor by inflation of the stomach with carbonic acid; the parts of a seidlitz powder being swallowed separately. Points for the confirmation of the diagnosis are found in the results of the examination of the stomach contents, the blood, and the urine. Notwithstanding all the work which has been done on the subject, and usually the very positive claims of inventors of tests of the finality of certain reactions and the pathognomonic significance of certain findings, Neusser considers no single point or even series of points as of absolute diagnostic significance. The absence of free hydrochloric acid in the stomach contents and the presence of lactic acid after the stomach has been washed out and a test meal has been given may mean much or little according to circumstances. The absence of all the digestive elements points to universal atrophy of the gastric glands rather than to cancer, though they may be absent as a secondary consequence of the latter.

Neusser attaches considerable significance to the blood findings in cancer. This is, however, to be expected as much of his own original work has been done on the blood. The absence in cases of carcinoma of the normal digestive leucocytosis which has been found to occur very constantly in Neusser's clinic even when patients retain their appetite and can take considerable quantities of albuminous food he considers seriously significant. When to this is added the poikilocytosis, the decrease in number and in hemoglobin contents of the red cells and the presence of nucleated red corpuscles we have what Neusser calls the chlorotic blood picture of carcinoma. The blood symptoms are of special importance for the differential diagnosis from tuberculous tumors in the stomach region which are usually accompanied by a cachexia anemia and loss of weight suggestive of cancer.

In the urine two points are looked upon as of significance—the acidity and the amount as compared with the amount of liquid taken. The hyperacidity of the urine secreted by carcinoma patients is extremely difficult to neutralize in the system. Large doses of carbonate of sodium are given for days in succession and if the urine does not become alkalin the result is considered as of diagnostic value. When considerably less urine is passed than the amount of liquid taken, that is to say, only one-half or slightly more, a non-absorption of liquid by the stomach is considered to be present and this would in cases with other suspicious symptoms point to cancer.

When all has been said, however, there is only a congeries of probabilities, and no absolutely pathognomonic symptom, or series of symptoms. With regard to surgical interference, Neusser considers it unwarranted whenever the tumor is found to move with the diaphragm in respiration. He determines this by endeavoring to fix the tumor in its lowest position of deep inspiration. Failure to retain the tumor under the fingers during expiration means that it is adherent to the spleen or liver, or that it has infiltrated a large part of the stomach, and these conditions contraindicate radical operation.

The following decorations for Austrian physicians from the Imperial government were announced on May 1st: Professor Anton Draschke, the Cross of the Royal Servian Order of St. Sara, of the first-class; Professor Karl Stoerk, the laryngologist, the Imperial Russian Order of St. Stanislaus, of the second class; Professor Friedrich Schauta, the obstetrician and gynecologist, the Princely Bulgarian Order of St. Alexander, of the third class; Dr. David Tyrnauer, a practitioner of Vienna, the Royal Servian Order of St. Sara, of the fourth class, and the Princely Bulgarian Order of Merit, of the fourth class.

Perhaps our republican American ideas do not permit us to appreciate these marks of royal imperial favor as much as we should. Perhaps, too, we do not realize all the honor that is thought to be conferred by them in the eyes of our Austrian colleagues. We cannot help but think that in the multiplicity of orders and classes, shared no doubt by others whose claims upon imperial favor may often be no more than political adroitness, or, to use the harsher terms, party treachery, or some of the many pretexts that ministers find for the recommendation of political favorites, the doctors' long years of work in practice and teaching are not very suitably rewarded.

Paris.

THE USE OF METHYL-BLUE IN THE TREATMENT OF MALARIA—RICARD'S AMPUTATION OF THE FOOT—SYME'S AMPUTATION OF THE FOOT—A CLASSIFICATION OF EIGHTY CASES OF APPENDICITIS—TESTING THE SERUM DIAGNOSIS OF CHOLERA.

AT the session of the Academy of Medicine held Tuesday, April 13th, **LAVERAN** presented to the Society a *résumé* of a monograph by Cardamatis of Athens, advocating *the use of methyl-blue in the treatment of malaria.* Methyl-blue cannot be considered a genuine substitute for quinin. It is recommended in cases in which, for some reason or other, the quinin salts cannot be given. As is well known, quinin, even in small doses, sometimes causes hemoglobinuria; it is also thought to be at times capable of producing abortion. In these cases methyl-blue may be substituted. It is also a much pleasanter remedy for children. The dose is from 10 to 15 grains daily. No ill effect other than that of cystitis has been noticed, and this subsides as soon as the administration of the drug is discontinued.

At the Surgical Society, held April 7th, **DELORME** spoke of seven cases of *Syme's amputation of the foot,* performed by himself. Six of these cases were for tuberculous arthritis and one for gangrene. The results were excellent in all cases. The old objection to this operation, namely, that it favored the retention of pus, is not any longer of force. The only disadvantage which it presents is that of slight shortening, but this is largely compensated for by the absence of recurrence.

RICARD described *an amputation of the fore part of the foot* performed by himself with good result. It is often necessary in performing Syme's and Roux's operations to resect a part of the tarsus in order to obtain a sufficiently long flap to cover the wound.

Ricard's method consists of the extirpation of the astragalus and the pushing of the os calcis into its place. Owing to the flattening of the heel which follows, flaps which before the removal of the astragalus were insufficient may now be united. If the calcaneum protrudes too far, a portion of it may be resected. The essential condition is firm coaptation of the anterior tendons of the leg with the posterior and plantar tendons so as to get a musculo tendinous ligament capable of keeping the calcaneum in position and of overcoming the contraction of the Achilles tendon. The operation is easy to perform and the calcaneum takes the place of the astragalus in its relations with tibia and fibula.

At the session of the Medical Societies of the Hospitals held April 9, **TALAMON** *reported upon eighty cases of appendicitis,* which he classifies as follows: (1) Acute appendicitis with immediately diffuse peritonitis (7 cases, all fatal—2 with, 5 without operation). (2) Acute appendicitis with partial suppurative peritonitis (14 cases, with 8 recoveries after operation; of the 6 other patients, 4 recovered, 1 died, and no information was obtainable of the sixth). (3) Acute appendicitis with partial fibrinous peritonitis, or plastic appendicitis (30 cases, all followed by recovery, 2 only after operation). (4) Simple parietal appendicitis (all cured by medicinal treatment). (5) Recurrent chronic appendicitis (in all but 3 of which operation was refused or put off; the 3 patients operated upon recovered completely).

The question of recurrence is intimately connected with that of intestinal disturbances antecedent to the appendicedic crises. In one-half of all the cases there was found no trace of any such disturbance, the attack occurring suddenly in the midst of perfect health. Talamon is in favor of a preventive operation after an attack of appendicitis only in children affected with the special variety of "family appendicitis." In these cases the liability to perforation appears to be greater, and operation is advisable at the first attack, no matter how slight it may be, as an appendicitis which just touches the peritoneum appears to be more frequently followed by perforation than a plastic appendicitis.

At the session of April 23, ACHARD and BENSAUDE described the results obtained by them in *testing the serum diagnosis of cholera.*. The serum of 14 Egyptian patients was investigated, and in 13 cases an agglutinating reaction was obtained with cultures of the cholera vibrio, in 2 on the first and in 3 on the second, in 4 on the third, in 2 on the fourth, in 1 on the sixth day of the disease, and in 1 on the twenty-eighth day of convalescence. The early manifestation of this reaction, if true, is of great practical importance; but as the history in these cases was not especially accurate, too much stress must not be laid on this point. The serum of six persons in good health and twenty-four suffering from various diseases was examined. Agglutinating reaction to an imperfect extent was found to be present in two cases of uremia. It is therefore still more necessary in cholera than in typhoid fever to admit as positive tests only those cases in which the reaction is very distinct. The examination is more difficult in cholera than in typhoid fever. On account of the film which follows on the surface of a broth-culture, it is usually necessary to employ an emulsion of microbes from fresh cultures on agar diluted with broth or a normal salt solution, and tested before the addition of the suspected serum, to make sure that agglomeration is not already present. The reaction usually manifests itself in from five to twenty minutes, and is fully as distinct as that obtained from typhoid fever.

Vienna.

STEREOSCOPIC PICTURES BY ROENTGEN RAYS—IDIOPATHIC ATROPHY OF THE SKIN.

At the session of the Imperio-Royal Society of Physicians held April 2d, EXNER showed Röntgen photographs made upon the stereoscopic principle. They were obtained by the use of two vacuum tubes so placed as to get a view of the object from different sides, as is done in making the ordinary stereoscopic photographs. By this method foreign bodies in particular can be exactly located, the appearance to the eyes being that of a plastic image, and not of a flat one.

NEUMANN showed two patients with idiopathic atrophy of the skin. In one, a man aged thirty-two, whose history dated back two years, there were limited areas of atrophy similar to skin atrophy of old age and situated in the breast, on the back, on the nates and over the femur, and on the thigh and leg. The affected skin became much wrinkled and in many places covered with scales. The spots on the abdomen presented a white center surrounded by a light prown pigmentation. Neumann looks upon this affection as an inflammation in the upper layer of the cuticle, but the number of cases is so small that it is impossible to draw a definite conclusion concerning the etiology of the trouble.

Dr. Ely Made Professor at Yale.—Dr. J. Slade Ely of the College of Physicians and Surgeons of New York has been appointed Professor of Theory and Practice of Medicine in Yale University.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

The Semicentennial Meeting, Held at Philadelphia, June 1, 2, 3, and 4, 1897.

(Continued from page 773.)

GENERAL SESSION.

FOURTH DAY—JUNE 4TH.

After the meeting had been called to order by the President, and the minutes of the preceding day's business had been read, the Chairman of the Committee on Arrangements announced the entertainments planned for the day.

The address on State Medicine was then delivered by DR. JOHN B. HAMILTON of Illinois, who took for his topic

THE PREVENTION OF TUBERCULOSIS.

In his preliminary remarks the great importance of this subject was dwelt upon, inasmuch as one death in every seven in this country was shown to be due to tuberculosis, the total deaths from this disease in the United States during the census years of 1850, 1860, 1870, 1880, and 1890 respectively, having been no less than 345,963. One-third of all surgical diseases, excluding injuries from mechanical violence, were also attributed to tuberculosis.

The speaker then mentioned that the proof of the heredity of tuberculosis had been established, and did not question the possibility of infecting animals by the injection of tuberculous milk; but maintained that, except in instances of udder tuberculosis, direct evidence of transmission of tuberculosis by milk in man by ingestion is not yet positive. The alleged infection of dog and cats by eating tuberculous meat was also considered uncorroborated by extended experiment.

The prevention of tuberculosis cannot be accomplished in a day, but with prompt measures on the part of health boards, and with the aid of the confidence and the understanding of the laity, its ravages may be made less; and it is highly important that the public should be fully educated to an understanding of its causes and methods of propagation. The necessity was pointed out of keeping before agriculturists, dairymen, stock-breeders, and butchers the fact that the bacillus tuberculosis is the sole cause of the disease, and of securing their complete cooperation with the health officer regarding preventive measures. The public should understand that tuberculosis is a preventable disease; the schoolmaster should understand the value of gymnastics and calisthenics in securing for his pupils immunity from the disease; and the consumptive should understand that he has no right to allow himself to become a center of infection by carelessness, or to marry while a subject of the disease.

It was noted that the cooking of tuberculous meat and the boiling of infected milk prevents their doing positive harm; that the innocuousness of a consumptive's breath has been demonstrated by the experiments of Bergey, and that the greatest source of danger lies in infection by the dried sputum.

The factors in successful prophylaxis were considered to be (1) the early diagnosis of the disease, as an aid to which, in cases presenting vague physical signs, the tuberculin test in carefully graduated doses is not less valuable in man than in the lower animals. (2) The guarding against infectious food and drink being issued to people anywhere. (3) Proper notification to the sanitary officer of the occurrence of cases of tuberculosis, especially walking cases, so that, in conjunction with the attending physician, thorough disinfection of bedding and sputum may be secured. (4) The prompt destruction of cattle proved to be tuberculous. (5) The discouraging of marriage between consumptives. (6) The treatment of tuberculosis in favorable climates, either in suitable sanataria, or in colonies.

In closing, brief reference to the advances in the treatment of tuberculosis was made, by measures such as the education of the laity regarding the disease, the use of hydrotherapy and pulmonary gymnastics, and proper medication, including serum-therapy.

At the close of his address, a vote of thanks was tendered Dr. Hamilton by the Association.

The following delegates to the International Medical Congress at Moscow, August, 1897, were appointed: Drs. G. S. Mitchell, J. E. Hyndman, Charles Dennison, A. M. Miller, H. L. E. Johnson, George M. Sternberg, D. L. Huntingdon, A. Marcy, Sr., H. D. Holton, Thomas MacDevitt, J. N. Quimby, and George R. Fowler.

A question was raised as to the expediency of sending a delegate to the coming meeting of the British Medical Association at Montreal, and the subject provoked considerable discussion *pro* and *con*, until it was ended by the President appointing Dr. Holton as the delegate to represent the American Medical Association at that meeting.

The Executive Committee reported that a prize medal valued at $50 was to be offered annually for the best essay on some scientific subject. This was approved by the Association, after the value of the medal had been increased to $100, and a committee of three to decide the competition was appointed. The question of railroad rates again came up for discussion, and it was voted that the President appoint within thirty days a committee of seven to report at the Denver meeting next year the rates offered by the railroads to various points, and that these rates be taken into consideration in the selection of a meeting place for 1899. The scheme of creating a relief association was discussed, but no more definite conclusion was arrived at than the reference of the topic to an appropriate committee for elaboration. The official approval of the Executive Committee was given to a resolution submitted to it by the Ophthalmological Section, recommending the general adoption of Credé's method for the prevention of ophthalmia neonatorum. It was concluded to defer until next year the consideration of the contemplated change of the name of the Section on Dental and Oral Surgery to that on Stomatology.

Other business consisted in the announcement of an annual prize of a medal valued at $100, offered by President Senn, for the best paper on some subject in surgery, to be awarded by competition; the decision to publish 3000 copies of the charter, constitution, and by-laws of the Association; the sending of a marked copy of that part of Dr. Keen's address relating to animal experimentation to every representative and senator in the United States Congress; and an unanimous vote of thanks to the citizens of Philadelphia for their hospitality during the meeting.

All business having been transacted, the newly elected president of the Association, Dr. George M. Sternberg, was introduced. In the course of a few remarks which he then made, Dr. Sternberg took occasion to state to the Association that the efforts which had been made to secure a representative of the medical profession in the cabinet of the President of the United States had been entirely unsuccessful, and that in his opinion the plan was impossible of accomplishment.

At the conclusion of President Sternberg's remarks the Association adjourned.

SECTION ON PRACTICE OF MEDICINE.

SECOND DAY—JUNE 2D.

(Continued from page 753.)

Dr. H. G. McCormick of Williamsport, Pa., read a paper, entitled

ONE HUNDRED CASES OF TYPHOID FEVER.

He divided his experience in the treatment of typhoid into two periods, in the first he had 24 cases with 3 deaths, and in the second 100 cases with 1 death. He had treated the first series according to the methods laid down in the text-books and by the Brand method, while in the treatment of the second series he had broken away from the old method and had treated his patients according to the dictates of reason. The longest time any of his patients had been under this treatment was twenty-one days, and the shortest, thirteen days. Of the 100 cases, 19 patients had hemorrhages, some of them several, and 11 had relapses. The treatment was not novel. The diet was carefully looked after, and no more food was given than could be easily digested. If it was not digested the quantity was decreased, or the diet was changed. He had found it better to give a mixed diet of milk, animal broths, and buttermilk than to keep the patient on milk alone. Each patient was given a tepid sponge bath twice a day. The bowels were kept thoroughly open, and for this purpose calomel was given every two hours until a free movement was obtained. The colon was washed out every day, the addition of salt to the enema sometimes being desirable. Water was given by the mouth as freely as the patient would take it. Two-drop doses of guaiacol were given every two hours for the antiseptic effect, and because this drug did not undergo changes in the intestinal canal but remained guaiacol at the ileocecal valve, just as it was at the mouth. In cases where guaiacol could not be borne, the carbonate of guaiacol was given instead. For weak heart, strychnin was given, and for hemorrhage, 15 minims of ergotole, hypodermically, and iced normal salt solution, rectal injections. Transfusion of normal salt solution was resorted to when the patients became anemic from the hemorrhages. In not a single case of hemorrhage was opium or acetate of lead given. He believed that no greater error was ever perpetuated than by the teaching that lead and opium should be given for hemorrhages, and a multitude of mounds in the cemetaries bore evidence to this fallacy. He admitted that opium checked the peristaltic action of the intestines, but at the same time it also dried up all the secretions and added to the danger of perforation of the bowel. For the reduction of fever, inunctions of from 10 to 25 drops of guaiacol were given, with excellent results. The use of the coal-tar preparations he regarded as dangerous, and should be condemned. He had seen two deaths directly attributable to the use of these drugs. He believed that typhoid fever, if seen prior to the seventh day, was capable of being aborted, and death should be a thing of rare occurrence.

He summed up as follows: Keep the bowels open, and keep the alimentary canal antiseptic; give as much food as can be digested; give plenty of water, both by the mouth and by the rectum; never give opium or acetate of lead. If these directions are followed out there will never be a death from typhoid fever.

Dr. Wm. Osler of Baltimore said that he had been very much interested in Dr. McCormick's paper, and he was glad to see that in many respects Dr. McCormick was still a young man, but he hoped that as he grew older his wisdom would increase with his experience. Dr. McCormick's record of 100 cases of typhoid without a death was certainly good, but it was not remarkable, for a record of 140 cases treated by the Brand method without a death had been made. There was another thing which made him think that Dr. McCormick was still an extremly young man, and that was that he had had 19 cases of hemorrhage in 100 cases of the disease and still clung to his method of treatment. If he (Osler) had 19 cases of hemorrhage from his method of treatment, he would change to another less risky one the very next day. Instead of opening the bowels as Dr. McCormick recommended, he (Osler) would like to open the minds of some of the medical men of the country and put a little common sense into them. He had also found that those cases of typhoid which ran the easiest course were those with the most confounded constipation.

Dr. Tyler of Pennsylvania said that he could not agree with Professor Osler that if he had nineteen per cent. of hemorrhage with any particular treatment he would quit that treatment right away. He took a different view of the matter, and if he had nineteen cases of hemorrhage out of 199 would consider that he was dealing with an unusually severe form of the disease, and a plan of treatment which gave ninety-nine per cent. of cures in such a case he would certainly stick to, notwithstanding Dr. Osler or "any other dogmatic professor."

Dr. J. M. Anders of Philadelphia said he wished to counteract any effect that might be created by the statement of Dr. McCormick that opium should not be given in typhoid fever. It was necessary, in case of hemorrhage, to put the body completely at rest, and this could only be done by means of opium.

Dr. J. E. Woodbridge of Cleveland replying to the attack made on his method of treatment by Dr. Upshur, said that the latter had not quoted him correctly in regard to some of the claims which he was said to have made for the treatment. Dr. Upshur had also said that reports of cases were of no value, but if there were no reports of cases how were physicians to decide whether a theory had merit or not? If, in one epidemic of a disease, there was thirty per cent. of deaths, and in another epidemic of the same disease there were no deaths under a different method of treatment, were not such reports of value? He was prepared for any amount of criticism on account of the publication of his method of treatment, and he had not made the statement that typhoid fever could be aborted until after he had been warned repeatedly that he would be—he hesitated for the proper expression, and Dr. Osler suggested "jumped on," which Dr. Woodbridge accepted. In any of the statements which he had made in reply to criticisms, he had never used Dr. Osler's name except with the highest respect, and as an exponent of all that was best in medicine, not only in this country, but in the world. He read a letter which he had just received from a physician speaking in high terms of the use of his method, and he stated that he had 1500 or 2000 more from physicians all over the country; so that if he was wrong in his belief in the efficacy of the treatment he advocated so were also these 2000 physicians. He stated that he regards diarrhea in typhoid as an evidence of the severity of the disease.

Dr. McCormick, in reply, said that somewhat early in his education as a physician he had conceived the idea that the curing of disease was the ultimate aim of the physician, and he had practised medicine on that principle ever since. Acting on this principle, no stronger impression of the necessity of abandoning the use of opium in the treatment of typhoid fever had appealed to him than an experience he once had in consultation with a young man who was fresh from the teaching of Professor Anders. He was treating a case of typhoid fever, and had given a hypodermic of morphin, when shortly afterward the abdomen became swollen and as tense as a drum. He then gave a second dose of morphin, and Dr. McCormick was called in consultation soon afterward. The patient was comatose at the time, and died shortly afterward. Dr. McCormick then said to the attending physician that he thought the second dose of morphin should not have been given and the patient might have survived the first; and he was met by the response that he had never been taught anything else than that opium should be given in typhoid. Surgeons had taught for a long time that opium should not be given in surgical inflammations, and he thought the same teaching was applicable to medical inflammations. There was a time when he believed that college professors were infallible and that text-books were infallible, but when his patients died under the treatment advocated by the college professors he had made up his mind that there was something wrong with the treatment.

Dr. Osler replied that college professors had eyes and ears, and some of them had common sense, and those who had not the latter quality, when their typhoid patients had hemorrhages, would not give opium.

THE CLINICAL SYMPTOMS, BACTERIOLOGIC FINDINGS, AND POST-MORTEM APPEARANCES IN CASES OF INFECTION OF HUMAN BEINGS WITH THE BACILLUS PYOCYANEUS

was the title of the next paper by **DR. L. BARKER** of Baltimore. This paper was a report of a bacteriologic investigation into the cause and properties of the common "green pus" or "blue pus" so often found on surgical dressings. French scientists had investigated the characters of the organism, and had found that the bacillus pyocyaneus was fatal to some animals not to others, and that while it was usually not fatal in human beings eleven cases had been reported in man in which death was due to this organism. It produced local toxic inflammations as well as general septicemia; it might cause eruptions on the skin, and would give rise to peritonitis, meningitis, pericarditis, and inflammation of the mucous and serous membranes generally. The bacillus pyocyaneus did not multiply in the blood. It might cause infection of the nervous system, and even lead to paralysis. The diagnosis of pyocyaneus infection could be made by finding the bacillus in the urine, and also by the peculiar odor of the patient. The prognosis was grave so far as the cases he had seen were concerned, but as it was probable that a great many individuals had pyocyaneus infection which was never recognized and recovered, it was probable that it was not as grave a condition as appeared from the cases he had had under observation. The treatment for the local manifestations of the disease was the same as for any other form of inflammation, with this exception: that there was a pyocyaneus antitoxic serum. This was the first serum made, antedating that of diphtheria and tetanus, but owing to the infrequency of the recognition of infection by this organism there was no demand for the serum, and consequently it was not obtainable in this country. In view of the probability of the more frequent recognition of the infection in future it was probable that the serum would be soon obtainable.

In reply to a question by **DR. OHLMACHER**, Dr. Barker stated that in several cases the bacillus pyocyaneus had been found pure, but in other instances it was mixed with the bacillus coli communis. He believed that it was generally found associated with other micro-organisms.

DR. F. A. PACKARD of Philadelphia next read a paper on

TRICHINOSIS AND THE TRICHINA SPIRALIS.

The case, of which this paper was a report, occurred in an Italian, aged twenty-four, a farm laborer. It was impossible to get a complete history from him, even by means of an interpreter, though it was learned that he had eaten a piece of raw pork sausage. On admission to the hospital he had a temperature of 101.2° F., with muscular pain in the thighs and legs. There a few granular casts in the urine. There were a few rose spots on the abdomen, which disappeared upon pressure and were regarded as suspicious. Previous to admission to the hospital he had had sweating for four days. A diagnosis of trichinosis was made. The temperature rose to 104.6° F. on several occasions and the pulse was accelerated, but not out of proportion to the fever. The blood was examined, but the examination was not as complete as it might have been. In the eye marked changes were found. An examination of the larynx was negative. Typhoid fever was excluded by the character of the temperature curve, the lack of splenic enlargement, etc. Rheumatism was considered, but no form of rheumatism would give such pains in the legs and thighs except the so-called muscular rheumatism. Influenza was ruled out with more difficulty, and a diagnosis of non-distinguishable tuberculosis was also excluded. A piece of the gastrocnemius muscle was cut out from one leg, and large numbers of the trichina were found. The operation gave so much relief to the distension of the leg that it was easy to get the patient's consent to the removal of a corresponding piece of muscle from the other leg. These pieces of muscle were fed to white rats, but the experiments were not yet completed. This was the fourth case in which he had made the diagnosis of tricinosis during life, but the only one in which he had been able to demonstrate the presence of the organisms in the muscles.

DR. J. M. ANDERS of Philadelphia read a paper upon

MYXEDEMA,

with a report of two cases. An interesting point in regard to one of the cases was that the glycerin extract of thyroid could not be taken, even in small doses, without the production of very distressing symptoms, while the powdered extract was well borne.

THE TREATMENT OF EXOPHTHALMIC GOITER AND OTHER VASOMOTOR ATAXIAS WITH PREPARATIONS OF THE THYMUS GLAND AND OF THE ADRENALS

was the title of a paper read by **DR. S. SOLIS-COHEN** of Philadelphia. A number of patients were presented who had been under treatment for varying lengths of time. The milder forms of Graves' disease were more common than the severer forms of Raynaud's disease. The symptoms were lack of co-ordination, heart murmurs, in some cases epistaxis and petechiæ; in others, bronzing of the skin, peculiar subjective symptoms, polyuria, etc. The disease was more common in women than in men, and was frequently associated with menstrual disorders. In most cases a distinct temperature relation could be made out, the patient being better in warm weather and worse in cold weather, or *vice versa.* Some of the phenomena of Graves' disease might appear transiently in normal healthy individuals. Such persons were apt to suffer from urticaria, due to eating certain food or taking certain drugs. As regards the treatment, this was somewhat confusing. One patient recovered, and others partially recovered from different methods of treatment. One patient who had partially recovered was given the thyroid gland in mistake for the thymus by the butcher who furnished them. This patient was so much improved by the thyroid-gland treatment that he left the hospital and was lost sight of for a time.

The discussion on this paper was of the running question and answer form, during which Dr. Cohen stated that the dose of the thymus gland began at 5 grains a day and increased to 30 grains in five or six doses. He did not believe that such a thing as thyroidism existed, bad results being due to faulty preparations of the gland. Instead of getting his glands from the butcher, he now got the best commercial article on the market. No other treatment was employed during the administration of the glands.

Dr. Judson Daland of Philadelphia gave a very interesting and instructive talk on the

PLASMODIUM OF MALARIA,

illustrated by a valuable series of lantern slides.

SECTION ON SURGERY AND ANATOMY.

THIRD DAY—JUNE 3D.

The first paper presented was by Dr. Z. J. Lusk of Warsaw, N. J., entitled

SOME ADDITIONAL FACTS RELATING TO SKIN GRAFTING, TECHNIC, ETC.

After calling attention to the details necessary for success in skin grafting, Dr. Lusk described a method which he had devised and employed with success. He uses epidermis which has been obtained by vesication caused by canthos or which separates after vesication from burns or scalds. He removes the cuticle carefully, keeping it flat, and preserves it in sterile gauze and cotton. The epidermis dries in a short time, after which it may be kept in this condition indefinitely. He has used epidermis obtained by the methods described, after it had been separated for more than one year, with perfect success. The graft is placed on the granulating surface in the dried condition, care being taken to apply the proper surface. The dressings should not be changed for several days after the operation. The advantages which Dr. Lusk claims for this method are the ease and facility of obtaining the necessary quantity of material and the better results obtained.

Dr. E. W. Holmes of Philadelphia read a paper on

THE TRAUMATIC FEVERS,

which he classifies as follows:

1. Primary fever. (*a*) Suppurative fever, acute and chronic; (*b*) true septicemia, acute and chronic.
2. Secondary fever. (*a*) Sapremia; (*b*) pyemia.

The speaker called attention to the confusion that has hitherto existed regarding these fevers. The first form described was that which is due to absorption of aseptic fibrin ferment from a wound which remains sterile. The symptoms are all mild. There is no change to be observed in the wound and the patient makes no complaint. At the end of the fourth or fifth day the fever subsides spontaneously. This form of surgical fever is in no wise under the control of the surgeon and does not reflect at all on his methods. The treatment is simple and consists in proper rest and suitable diet.

True suppurative fever is due to the presence of microorganisms in the wound and to absorption of their products into the system. The condition is announced by a chill, which is followed by fever and sweat, and an examination of the wound will usually reveal pus. In many cases pus forms without the occurrence of a chill. This is probably explained by the local condition. If the pus forms slowly there is considerable infiltration and pressure, the lymphatic channels are compressed or blocked up, and they are thus prevented from conveying the products in the wound to the general circulation. If, on the other hand, the pus forms rapidly, and before there is time for the formation of a protecting wall, the lymph channels draining perfectly soon convey the poison to the system and evidences of constitutional reaction is observed early. In the condition just described there are no germs in the blood. In true septicemia the condition is due to micro-organisms in the circulation. The general symptoms noted in the previous form are observed in this condition to a more marked degree.

Sapremia is the form first described, one form of which frequently follows surgical operations. The condition is, however, too common in obstetric practice. The local treatment of sapremia is important. If the local conditions are improved, the symptoms rapidly subside.

Pyemia, the author thinks, is set apart from the other conditions on account of the abscesses which form in various regions of the body, besides the profound depression and typhoid condition which is more marked in pyemia than in any other of the traumatic fevers. The infection passes along the vascular and lymphatic channels. Pyemia is the result of a double infection—a pyogenic and a saprophytic. The symptoms appear about the second week. There are repeated chills, followed by fever and exhaustive sweats, a typhoid condition, hyperesthesia of the skin, and local abscesses. The mind remains clear unless an abscess forms in the brain. The rise in temperature coincides with the chill, the sweat quickly following.

The term arterial pyemia is applied to the lodgment of a fragment of a white blood clot at some point in the circulation, and should be dropped, as it tends to confuse the subject.

After the afternoon meeting had been called to order Dr. J. B. Murphy asked to be released from the position of Chairman for the coming year, to which he had been elected on the previous day, as he had been appointed to give the address in surgery at the next meeting. Dr. Murphy's request was granted. As the nominating committee had disbanded the Section proceeded to the nomination and election of officers for the ensuing year, which resulted in the selection of Dr. William L. Rodman of Louisville, Ky., for Chairman, and Dr. Clayton Parkhill of Denver, Col., for Secretary.

Dr. W. J. Mayo of Rochester, Minn., read a paper on

CICATRICIAL STENOSIS AND VALVE FORMATION AS A CAUSE OF PYLORIC OBSTRUCTION, WITH A REPORT OF FIVE CASES RELIEVED BY OPERATION.

He believes that stricture of of the pylorus caused by a healed gastric ulcer or by a valve formation is of more frequent occurrence than has been supposed. The diagnosis of pyloric obstruction is usually easy, the more or less regular vomiting of all the food ingested serving to establish the presence of this condition. If the stomach be inflated with air it may then be outlined by the usual aids in physical diagnosis—inspection, palpation, percussion, and auscultation.

The speaker prefers a medium abdominal incision, beginning at the ensiform cartilage and carried down as far as necessary, The Heineke-Mikulicz operation was advised for all cases of pyloric obstruction of benign origin to which it can be applied. In rare instances of marked cicatricial contraction the method is inapplicable.

Loretta's operation, the author stated, had failed to give permanent relief in a large proportion of cases. Pylorectomy, he said, should be performed in but few cases, and then only for the clearest indications, on account of the high mortality. Gastro-enterostomy for non-malignant stricture has given a mortality of about fifty per cent., and is therefore to be avoided in all cases in which pyloroplasty can be performed. The unequal thicknesses of the walls of the stomach and intestine is a weak point in this operation.

The after-treatment of these cases consists in the use of morphine to control peristalsis, rectal feeding for some days, and strychnin, if needed.

DR. L. H. ADLER, JR., of Philadelphia read a paper on the

PRESENT STATUS OF THE INJECTION TREATMENT OF HEMORRHOIDS.

The remarks were applied particularly to the condition known as internal hemorrhoids. The preparation used was that recommended in Agnew's "Surgery," and consists of acetate of lead, 2 drams; glycerin, 1 ounce; Calvert's No. 1 carbolic acid, 1 ounce, and water, 2 drams. The first two are mixed and allowed to stand twenty-four hours. The water is then added to the carbolic acid and sufficient of the lead acetate mixture to make the preparation measure two ounces. The author emphasized the necessity for the minutest care in the compounding of this mixture in order to secure the best result. It was also stated that it is essential to use the No. 1 acid. Since the speaker has been using this method he has been particularly pleased with the uniformly satisfactory results.

DR. T. S. K. MORTON of Philadelphia read a paper upon

TRANSPERITONEAL LIGATION OF THE ILIAC ARTERY, WITH REPORT OF CASES.

He has been able to collect twenty-eight cases of this operation, from literature and by correspondence. His own case was one of aneurism of the femoral artery, extending above Poupart's ligament, and therefore required the iliac ligation. The patient recovered.

DR, S. F. FRIEND of Milwaukee read a paper on

THE ETIOLOGY AND CLASSIFICATION OF TUMORS,

which was based upon a consideration of histology and pathologic anatomy.

DR. HOWARD LILIENTHAL of New York read a paper on

SERUM-THERAPY IN ACUTE SURGICAL INFECTIOUS DISEASES.

He referred to a number of cases in which the antistreptococcic serum had been used with apparent benefit. He particularly advocated its use as a prophylactic in cases in which septicemia might be expected to follow an operation. A similar recommendation has been made by Watson Cheyne, who has reported three cases so treated. While the serum is being used every proper surgical measure should also be employed, with the view of bringing about recovery. The author differs with those who contend that no such condition as immunity really exists.

DR. GEORGE R. FOWLER of Brooklyn read a paper on

THE DIFFERENTIAL DIAGNOSIS OF SURGICAL LESIONS IN THE RIGHT HALF OF THE ABDOMEN AND PELVIS.

The most common surgical condition of this region is appendicitis. After describing the usual symptoms Dr. Fowler called attention to the variations that might occur. Vomiting is not infrequently absent. The pain may be general over the abdomen rather than located above the umbilicus in the early stages of some cases, or in the right iliac fossa from the outset. Opium may obscure the symptoms, upon which a diagnosis might be made.

A perceptible tumor from appendicitis is almost never present before the end of twenty-four hours, and usually not until the end of forty-eight or seventy-two hours. The appendix may lie in any direction and the symptoms will depend upon the particular location of the organ. Among the commoner conditions that may simulate appendicitis the author mentioned cholecystitis, impaction of fecal matter, tumor, and in the female, tubo-ovarian diseases. About eighty per cent. of the cases of appendicitis occur in men. The difference between the symptoms of appendicitis and of tubo-ovarian disease, was dwelt on at some length. The onset in the former is usually acute; in the latter a history of previous trouble will generally be obtained. Vomiting is common in appendicitis and rare in disease of the adnexa. The tenderness in appendicitis is generally well localized, while in tubal disease it is more general. In the former the tenderness on palpation over the right iliac fossa is acute and much less sharp by vaginal touch. In the latter the external tenderness is comparatively slight, but very marked by vaginal examination. Chill is infrequent in appendicitis, but common in the acute exacerbations of disease of the adnexa. Rigidity of the abdominal wall is marked in appendicitis, and usually absent in tubo-ovarian inflammations. The latter, the speaker regarded, as a most valuable distinction. The tumor in a case of appendicitis appears at the end of two or three days, while it is usually present upon the first examination in pelvic inflammations. A careful consideration of these points will usually lead to a correct interpretation of the diseases in the right side of the pelvis and abdomen in women.

FOURTH DAY—JUNE 4TH.

DR. A. E. TRACY of Boston presented papers upon the following subjects:

(*a*) THE TREATMENT OF COLLES' FRACTURE. (*b*) THE PASSING OF PLASTER.

The author stated that before the work of Colles, the fracture which bears his name was considered either a posterior dislocation of the hand or an anterior dislocation of the radius. In regard to the treatment of the Colles' fracture, the speaker recommended, after reduction, the application of a simple splint, and gave his preference to a wood-fiber molded splint. The rules governing the treatment of this fracture he summarized under three heads: (1) Reduction. (2) Protection with a simple splint. (3) Passive motion of the fingers on the first day and of the wrist on the fifth day. In referring to the second portion of the title, Dr. Tracy claimed that plaster of Paris was frequently a source of danger to the vitality of the limb to which it is applied, and that it is uncertain in regard to retaining the fragments in position in the treatment of fractures. He also claimed that the plaster of Paris did not fix the parts beneath; as the swelling subsides considerable motion is permitted. It also prevents inspection of the part, which the speaker said was desirable in all cases of fracture. Besides, a permanent dressing, such as plaster of Paris, by preventing passive motion of the joints, tends to cause a marked degree of stiffness that is slow to disappear and troublesome in the convalescence. If, by any chance, the fragments should become displaced, the fact would not be known in the case of a plaster dressing, and union would take place in a faulty position.

The advantages claimed for the wood-fiber which he described are that by making a proper pattern the material may be molded accurately to the surface of the body without any intervening material. The splint is simply dipped in water, placed in position, a roller bandage applied, and the part is fixed immediately. The bandage may be removed as often as necessary and the part inspected, the splint having become molded and dried, fits accurately, and may be reapplied without disturbance. Passive motion of the joints may be employed early, and the lightness of the material used in the splint makes it a more comfortable dressing than plaster of Paris. The wood-fiber splint is applicable to every portion of the body, it is porous, clean, does not irritate the skin, and requires no padding.

Dr. Fowler, the chairman of the committee appointed on the previous day to consider Dr. Senn's offer of a gold medal for the best essay on any surgical subject, presented at the annual meetings, reported as follows:

(1) That a gold medal of suitable design be awarded annually for the best essay before the Section on Surgery and Anatomy each year. (2) The medal to be known as the "Nicholas Senn Prize Medal." (3) The composition must be completed and forwarded to the committee appointed by the Chairman of the Section at the last meeting, at least three months before the date upon which it is to be presented. (4) Each essay is to be signed by a motto, or devise, and shall be accompanied by a sealed envelope bearing the same motto, or design, and containing the name and the address of the author. (5) The envelope shall no be opened until after the paper has been read before the Association when the name of the author will be announced. (6) Essays shall be presented in competition for this prize but once. (7) The successful essay to become the property of the Association. (8) The successful competitor shall be known as the "Nicholas Senn Gold Medal Essayist." (9) The competition shall be announced in at least four issues of the journal of the Association. (10) Not more than two papers shall be given the award of honorable mention in any one year. These papers also become the property of the Association. (11) The medal shall be conferred at the general meeting. (12) The competition for this prize is open only to those who are members of the Association at the time the essay is offered.

Section on Obstetrics and Gynecology.

Second Day—June 2d.

(Continued from page 756.)

Dr. Thos. H. Manley of New York read in abstract a paper on

RENAL SUPPURATION, CATARRHAL, SPECIFIC, AND TRAUMATIC, AND THE VALUE OF MICRO-URINALYSIS OF THE URINARY SEDIMENT AS AN AID TO DEFINITE DIAGNOSIS.

He described his paper as a few notes on a class of lesions which, until comparatively recently, has been practically unstudied, and which as yet are not properly interpreted. "Surgical Kidney" is a designation which carries with it a very pernicious significance, since it always implies the necessity for a surgical procedure. With but few exceptions, renal suppuration begins in one kidney, right or left. Tuberculosis of the kidney, according to some authorities, is never primarily bilateral. He possesses statistics bearing on the frequency of these lesions of the kidney, the classification of suppurative renal lesions, the course they pursue, the diagnosis and treatment. It is now very generally conceded that renal suppuration depends often upon an alkaline fermentation of the urine. Delafield believes that pyelonephrosis commonly involves both kidneys, and that such patients invariably die. Others do not admit this. Some say that if it is a bilateral condition it is much more on one side than on the other. Manley believes that renal suppuration is much more common than is generally supposed. In many cases of so-called lumbago or nephralgia the true condition is one of suppuration. The most common cause of abscess of the kidney is trauma from the presence of a calculus. A morphologic and bacteriologic examination of the urine constitutes a valuable means of study of this condition. While not always able to settle upon the precise site of the disease, we can, by these means, do so in a large number of cases. Masses of micrococci grouped together in the urine indicate septic infection of the kidneys. The presence of pus in the urine in considerable quantity is always an index of serious trouble at some point in the urinary tract. He has had but one case during the past year in which, by *post-mortem* examination he could verify the diagnosis made during life. He is surprised that the morphology of the urine has not been better studied by physicians. Pyelonephrosis is by no means incurable by proper methods, and surgical treatment is not always required. Do not be content with only a single examination of the urine. The pus varies in amount and in the time of its appearance. The presence of cystitis, and particularly of intermittent cystitis, is suggestive of renal disease. This cystitis is due to a descending infection. The epithelia along the course of the urinary tract must be studied, In women, the urine should always be drawn by a sterilized instrument. In pyelonephrosis the kidney is invariably displaced, and can be mapped out on palpation. He objects emphatically to exploratory incisions; they imply weakness on the part of the surgeon. The surgeon should not operate unless he is prepared to go ahead and complete the operation.

DR. M. ROSENWASSER of Cleveland read a paper on the

TREATMENT OF CIRCUMSCRIBED PELVIC HEMORRHAGE,

in which he distinguished emphatically between free hemorrhage and the so-called conditions of pelvic and abdominal hematocele. He stated that not more than forty per cent. of circumscribed hemorrhages due to extra-uterine pregnancy require operative procedures. In these circumscribed cases he insists upon "vigilant delay," the patient being closely watched in a hospital, and rarely has he been compelled to resort to operative treatment. He concludes that, unless a circumscribed hemorrhage requires immediate operation when first seen, the case can be watched usually with good results. Operation is necessary only for sepsis, recurrent hemorrhage, return of the tumor, non-absorption of the effusion, and pressure upon the viscera. The abdominal section is to be preferred to the vaginal incision.

DR. HOWARD A. KELLY of Baltimore read a paper on

ADVANCES IN THE TREATMENT OF FIBROID UTERI.

He said that the next great wave in gynecology will be conservatism in everything but malignancy, and he is here to-day to recommend the conservative treatment of fibroids. He declares the perfect feasibility of extracting from six to thirty, or more myomata, large or small, from the uterine wall closing the wounds with sutures, and leaving the woman a serviceable uterus. It is far more difficult to take out a tumor than to remove the uterus with the tumor. It is not a routine procedure, as is hysterectomy. The hemorrhage also is more difficult to control. Nevertheless, it is the operation of choice. If the patient is in good general condition and under thirty-seven years of age, myomectomy should be done. He would not do it in women who are run down or older. A slight cut is made into the white tissue of the tumor, which is then dissected out with forceps. The fingers should not be used for this purpose. If the tumor is large, the wound should be closed *pari passu* with the removal of the growth. He has cut loose the bladder to remove subvesical tumors of the uterus. A buried catgut suture should be applied so as to leave no dead spaces, and the angles of the wound especially must be closed to prevent bleeding. The tissues should not be handled; this will avoid sepsis. The assistants should use rubber or lisle-thread gloves. He has made as many as seven or nine incisions into the uterus. As a rule the uterine cavity is not opened, although in some cases it is. This, however, is not a serious complication. In one case the entire anterior wall of the uterus was removed; the cavity was closed, however, and the patient has since menstruated normally. All the cases have done well. This conservative operative measure means much to the patient, possibly motherhood.

DR. HENRY O. MARCY of Boston read a paper, entitled

THE CLOSURE OF WOUNDS OF THE BLADDER BY THE USE OF THE BURIED TENDON SUTURE, WITH SPECIAL REFERENCE TO A NEW METHOD FOR THE CURE OF DIFFICULT CASES OF VESICOVAGINAL FISTULA.

He inserts the sutures by means of a fine needle, which penetrates the intestine or bladder to, but not through, the mucous coat. The included structures are held together in a double loop from side to side. The submucous insertion buries the suture in vital tissue, and the mucosa is inverted into the bowel or bladder. No undue force is used in tightening the sutures. An external line of intraperitoneal sutures folds the peritoneum so as to enclose the sutures. As regards fistulæ, the action of the muscular fibers in the vaginal wall prevent the union of the fistular edges. He would, therefore, freely dissect the muscle loose and then close by means of buried sutures in the manner already given. He would use a single tendon suture with a Hagedorn needle making a lacing stitch, whereby the sides of the wound are approximated. The bladder mucosa is thus inverted. Rectovaginal fistulæ are operated upon by the same method. The rectum is first dissected freely from the vagina and the two closed separately. We are indebted to Kelly for the revival of the suggestion of catheterizing the ureters preliminary to the closing of large vericovaginal fistulæ. Marcy especially lays stress on the lateral approximation of the tissues of the median line.

DR. C. S. BACON of Chicago read a paper on

THE MIDWIFE QUESTION IN AMERICA,

in which he said that in Germany the question of the improvement of midwifes has recently attracted much attention, as also in England and France. In this country the State boards and the boards of health have made some efforts in this direction. He would not abolish midwives, but would regulate their education and registration. There are almost 900 midwives in Chicago, who attend 25,000 births in a year. A prevalent idea is that midwives educated in Europe are better than those educated here. Ilinois and Missouri require a course of five-months' training in obstetrics before a certificate can be issued. An efficient system of midwife control and regulation is essential; otherwise the midwives degenerate. The mortality rate from puerperal sepsis has decreased in the hands of midwives, but is still very high. No midwife can manage properly complicated cases, but they can attend normal labors. The practice of abortion has become a serious question, and it is due largely to improper supervision of midwives. He believes that midwives are needed. The State boards and the boards of health should take in hand the regulation of these women. A ten-months' course should be given in a midwife school in connection with a regular school of medicine.

SECTION ON DISEASES OF CHILDREN.

THIRD DAY—JUNE 3D.

(Continued from page 771.)

Dr. **Bedford Brown** of Alexandria, Va., read a paper, entitled

NEW METHODS OF RESUSCITATING STILL-BORN AND FEEBLE-BORN CHILDREN,

in which he recommended hypodermic injections of four or five drops of whisky and one drop of tincture of belladonna, in each arm, and hot water rectal injections. Hot water, hypodermically, was advised in cases of marked cyanosis.

THE TREATMENT OF HERNIA IN INFANCY AND CHILDHOOD

was the subject of a paper read by Dr. **Wm. B. Coley** of New York. He said that the treatment of the inguinal form of hernia in infants should be begun at once upon the discovery of the condition by the application of a truss. The steel truss is more satisfactory than a pad and bandage, and it should be worn day and night for at least two or three years. Operation is not advisable before the fourth year.

Dr. **A. Ernest Gallant** of New York read a paper, entitled

VAN ARSDALE'S TRIANGULAR SPLINT IN FRACTURES OF THE SHAFT OF THE FEMUR IN INFANTS AND YOUNG CHILDREN,

in which he recorded his own observations and gave an exhaustive review of the literature on the subject. An interesting demonstration was also made of the application of the triangular splint. The requisites for an efficient splint in fractures of the femur in young children, as mentioned by most writers, are rest, an apparatus which does not hurt, or become wet and soiled or need frequent readjustment, and to this the writer adds that the child must be moved about or, if old enough, allowed to move about itself. The triangular splint is made of thick cardboard, and is adjusted in the following way: The length of the uninjured thigh from the middle of the groin to the end of the femur is measured, and a figure is outlined upon the cardboard resembling two spades, as shown on playing-cards, united at the points, the length of each of the four sections being equal to that of the child's thigh, the widest portion equaling about two-thirds of the circumference of the thigh. This figure is then cut out with a knife. The cardboard is moistened on one side and folded so as to form a triangle of about 60 degrees, and fastened in that position by means of adhesive plaster. The abdomen and thigh are then covered with cotton which is held in place by a gauze bandage. The splint is adjusted by placing the triangle in the angle formed by flexing the thigh, allowing one flanged portion to embrace the thigh while the other rests upon the abdomen. It is secured in place by means of a muslin bandage which is carried through the splint, around the body and around the thigh. The hips and thigh are then encircled with starch or crinolin bandages. The leg must be bandaged from the toes to the knee to prevent swelling. The splint may be removed at the end of the third week. Friction should then be employed to restore muscular tone, the strokes always being toward the trunk.

Dr. **James P. Fiske** of New York read a paper, entitled

THE APPLICATION OF THE AMBULANT METHOD TO FRACTURES OF THE LEG IN CHILDREN.

The ambulant plaster cast is applied as follows: After reduction of any deformity the limb is held by an assistant, the foot being flexed to a right angle, and the foot and leg are bandaged with a muslin roller from the toe tips up to and surrounding the tuberosity of the tibia. This bandage, as well as the cast, may extend in children well up on the thigh, as the effectiveness of the cast as a walking splint depends largely upon how firmly it grasps and supports the enlarged upper end of the tibia. Over the muslin roller the plaster bandages are applied in the usual manner, being thicker about the ankle and also at the superior circumference of the splint where in walking it largely supports the weight of the body. No padding is used, the splint exerting equal pressure at all points. A considerable experience in the use of plaster dressing is requisite to have the cast applied in an efficient manner. It has been thought that as the tuberosity of the tibia is not developed at this age to the extent that it is in adult life the ambulant cast is not applicable to children. This view is entirely erroneous, as it may be applied at all ages and in various conditions, not only in fracture of the leg but in tuberculous disease of the ankle-joint, including resection of the ankle-joint, and also in osteotomy cases involving both tibia and fibula.

Dr. **Thos. Chas. Martin** of Cleveland, O., read a paper, entitled

DIFFICULT DEFECATION IN INFANTS.

Straining at stool is explained because of imperfect development of the anatomic structures concerned in the mechanism of expulsion, which are the following: (1) The infant's lower gut is muscularly deficient. (2) Its mobility within the abdomen is obstructive to defecation. (3) The semilunar valves of the rectum are obstructive. (4) The infant's anus not being sufficiently expansible is also obstructive. The wall of the infant rectum and sigmoid flexure is thin as compared with that of an adult. It is impossible to distinguish the longitudinal muscular bands which are so apparent in the gut of the adult.

The relations of the peritoneum to the rectum in the infant contributes to the difficulties of defecation; also, the relatively great length of the descending colon. The mesentery of the sigmoid flexure and rectum is disadvantageously long. The pelvic outlet in the infant is so contracted that the limits of anal expansion are such as to almost defeat the passage through it of other than fluid feces. The average transverse diameter of the newly born infant's pelvic outlet is but a little more than half an inch.

The paper by Dr. E. Stuver of Rawlins, Wyoming, entitled

THE INFLUENCE OF OUR PRESENT SCHOOL SYSTEM ON THE HEALTH AND DEVELOPMENT OF THE CHILD

was read by the secretary in the absence of the author.

The paper, entitled

INFANTILE CONSTIPATION,

by Dr. J. W. Byers of Charlotte, N. C., was read by title.

Dr. Louis F. Bishop of New York City read a paper on

THE EARLY RECOGNITION AND TREATMENT OF DEFECTIVE DEVELOPMENT OF CHILDREN.

Dr. Jas. J. Concannon of New York City read a paper, entitled

ABNORMAL RESPIRATION IN INFANTS FROM OBSTRUCTION IN THE UPPER AIR PASSAGES.

Fourth Day—June 4th.

Dr. I. N. Love of St. Louis addressed the Section with a plea to organize a National Pediatric Society, with the object of disseminating a knowledge of diseases of children, making it distinctly a national organization, its members consisting of teachers and instructors in pediatrics. Upon motion of Dr. Henry E. Tuley the consideration of this subject was indefinitely postponed.

Dr. J. W. Byers of Charlotte, N. C., read a paper, entitled

INFANTILE CONSTIPATION.

The form described was the habitual constipation associated with, or ascribable to, defective conditions connected with the digestion and assimilation of certain elements in the food.

Dr. Harriet E. Garrison of Dixon, Ill., read a paper, entitled

THE BELLADONNA TREATMENT OF PERTUSSIS.

She reported several interesting cases, the method of treatment being one-half-drop doses of tincture of belladonna repeated every hour, unless marked dilatation of the pupils was produced. In other cases granules of atropin sulphate, grain $\frac{1}{250}$, was administered at bedtime, with bromid of sodium. In one case in which there was a hysteric element, the sodium was replaced by asafetida. The conclusions reached were that belladonna *per se* will relieve pertussis, and that a neurotic element is often present when there is a severe cough afterward. The younger the child the better the belladonna acts in relieving pertussis. It takes proportionately a larger dose to produce toxic symptoms in a child than in an adult.

Dr. Jos. Wm. Stickler of Orange, N. J., read a paper, entitled

THE MANAGEMENT OF CHILDREN WITH INHERITED TUBERCULOUS DIATHESIS.

Dr. Jas. C. Johnston of New York read a paper upon

SKIN GRANULOMATA IN CHILDREN: THE TUBERCULOSES.

Dr. Mary E. Baldwin of Newport, R. I., read a paper, entitled

THE CARE OF THE BABY'S EYES IN THE PERAMBULATOR.

Dr. H. H. P. Leuf of Philadelphia read a paper, entitled

A PLEA FOR A MORE COMMON-SENSE TREATMENT OF SICK CHILDREN,

after which the section adjourned.

Section on Materia Medica, Pharmacy, and Therapeutics.

Second Day—June 2d.

(Continued from page 759.)

Dr. N. S. Davis of Chicago read a paper on

THE THERAPEUTIC PROPERTIES OF ALCOHOL AND THE REASONS WHY THE FERMENTED AND DISTILLED LIQUORS USED AS BEVERAGES SHOULD NOT BE RECOGNIZED IN THE PHARMACOPEIA AS MEDICINAL AGENTS.

He first laid down the broad proposition that pure ethyl-alcohol is an active poison, and reviewed its physiologic effects upon the tissues and organs of the body. He claimed that the supposed tonic and restorative effects are based solely upon the sensations and movements of the patients, but when the improvements of analytic chemistry were brought to aid the elucidation of the problem, it was found that alcohol retards the natural metabolic changes, lessens the processes of oxidation and elimination, diminishes nerve sensibility, and when repeated from day to day induces cell and tissue degeneration. It also affects the action of the cells of the brain and reduces intellectual force and mental restraint. The various alcoholic beverages all owe their activity to ethyl-alcohol, any addition being either harmful or for mere flavoring purposes. Brandy, whisky, and wines are prescribed for their alcoholic constituent, which, however, varies very greatly. In no other powerful agent used in medicine would such indifference be shown to the variation in strength of the active ingredient. He therefore advocated the dismissal from the Pharmacopeia of all this class of agents, and substituting dilute alcohol in their place. It would be a long and very important step in advance both in the interests of scientific accuracy and of humanity, if all physicians, when they think alcohol is needed, would prescribe it in the manner just indicated. In the next revision of the Pharmacopeia if only alcohol of standard strength should be retained, to the exclusion of all fermented and distilled liquors, and if these changes were adopted and carried into general practice, the result would be a more complete separation of both pharmacists and physicians from connection with and responsibility for, the general traffic in and uses of the various alcoholic liquors now in popular demand.

The discussion was carried on by Dr. Remington of Philadelphia, Mr. Thompson of Washington, Drs. Shoemaker of Philadelphia and Eccles of Brooklyn, Fite of

New York, King of Pittsburg, F. E. Stewart, and Davis, the general tone being in favor of the position taken by the reader of the paper.

Dr. Stewart, chairman of the delegates from the American Pharmaceutical Association, offered the following resolution on behalf of the delegation:

Whereas, As the medicinal properties of spiritus frumenti and spiritus vini gallici are due solely to the alcohol they contain, and alcoholic stimulation can be better achieved by the use of pure alcohol, properly diluted, and with less danger of the patient acquiring an alcoholic appetite than by administering either of the above-named beverages, it is therefore

Resolved, That the Section on Materia Medica, Pharmacy, and Therapeutics of the American Medical Association recommends that spiritus frumenti and spiritus vini gallici be dropped from the United States Pharmacopeia in its next revision. This was unanimously adopted, and referred to the Executive Committee.

Dr. F. E. Stewart of Detroit read a paper, entitled

IS IT ETHICAL FOR MEDICAL MEN TO PATENT MEDICAL INVENTIONS?

The author reviewed the question of the origin of patent rights and the present practice with regard to patents, which restrict the use of any patented article, and concluded that it was not ethical for a physician, whether belonging to the Association or not, to own a patent on medical inventions. He also incidentally discussed so-called patent or proprietary medicines, and insisted that if the laws now in force were obeyed, traffic in this class of merchandise would cease entirely.

Dr. William Trelease of St. Louis read a paper on

MEDICAL BOTANY.

In this communication the author spoke of the value of well-arranged botanic gardens for the purpose of teaching medical botany. He also spoke of the great value of a text-book, which would enable the student to identify trees and plants at other times than when in flower.

The following officers were elected for the following year: Chairman, Dr. John V. Shoemaker of Philadelphia; Secretary, Dr. C. C. Fite of New York. Executive Committee: Drs. Frank Woodbury of Philadelphia, F. E. Stewart of Detroit, and Warren B. Hill of Milwaukee.

Third Day—June 3d.

The Section met at the College of Pharmacy by invitation of the Trustees. The first report of the Committee on Joint Investigation with the American Pharmaceutical Association was read.

Dr. R. W. Wilcox of New York read a paper, entitled

THE PHYSIOLOGIC AND THERAPEUTIC ACTION; A CLINICAL STUDY OF STROPHANTHUS.

The communication was the second on the subject, the first having appeared in *The American Journal of the Medical Sciences* for May, 1897. Success in the administration of strophanthus requires: (1) an active, well-made preparation from a reliable source; (2) avoidance of its use in the case of fully or over-compensated hearts, in those which present advanced muscular degeneration, or mechanical defects of high degree; (3) the use of not too large or too frequently repeated doses. A dose of five drops of this preparation, three or four times a day, is sufficient. In a study of twelve cases, which was the basis of the paper, the author made use of a tincture of strophanthus kombé (variety *pubescens*) made by Parke, Davis & Co., according to the terms of the United States Pharmacopeia, and standardized by physiologic methods. A study of the effects upon the circulation shows that the line of ascent, in the pulse tracing with Dudgeon's sphygmograph, becomes longer and more perpendicular, the distance between the successive apices longer, the decrotic wave disappearing, and the irregularities being almost always overcome. In other words, the heart-beat becomes stronger, its rate slower, and rhythm more regular. This change took place without any change in blood tension other than could be justly attributed to a more powerfully and evenly acting heart. A number of tracings were shown indicating increased power in the heart. There was no effect upon the blood-vessels, strophanthus being a pure heart tonic. Experiments made with fluid extracts from different varieties showed that they varied in their physiologic effects, and in most instances caused gastric disturbance which did not follow the use of a good tincture, or of the strophanthin itself in tablets (gr. $\frac{1}{250}$) for hypodermic use.

The advantages of approved preparations of strophanthus over digitalis are: (1) greater rapidity of action, (2) absence of so-called cumulative effects, (3) non-interference with the caliber of the arteries. In conclusion, he called attention to the marked safety of strophanthus as a heart tonic for the aged, the nephritic, the gouty, and the atheromatous. It is the best cardiac remedy for children.

Dr. E. M. Houghton of Detroit read a paper, entitled

THE PHARMACOLOGY OF STROPHANTHUS.

The active principle of strophanthus is contained in variable quantities in different species and different samples. One specimen was found to be one-hundred times as strong as another which was claimed to be a chemically pure article. Strophanthin in a nerve and muscle poison, primarily. In therapeutic doses, it slows the pulse, lengthens the cardiac systole and diastole, increases blood pressure, and the efficiency of the cardiac muscle. In toxic doses, it produces rapid paralysis of the heart. When brought in contact with the conjunctiva, strophanthin exerts a local anesthetic influence ten times as great as cocain, but its use is liable to be followed by inflammation or even ulceration. It causes slight lowering of the temperature in normal animals. It is a cerebral sedative, and sleep is one of the most constant symptoms in dogs, rabbits, and guinea-pigs under full doses of the drug. Strophanthus produces much less disturbance of the stomach than does digitalis, acting locally as a stimulant or irritant to the gastro-intestinal mucous membrane. Like digitalis, it stops the heart in systole. The author's experiments on various animals convinced him that no constriction of the vessels is produced by therapeutic doses of strophanthus. The increased blood pressure must be due mainly to direct action upon the heart or upon the nervous mechanism controlling the heart. The pulse is made slower and more full and regular; there is no constriction of the arterioles or any especial action upon the vasomotor mechanism, the diuresis and other important results being due mainly to improved circulation. Its special advantage over digitalis consists in the facts that it does not produce gastric disturbance; it does not show cumulative action; it acts more quickly and with greater certainty, and owing to its ready solubility it is better for hypodermic administration, and the strength of its preparations are more easily standardized. As regards the ordinary dose, three to five drops of a five-per-cent. tincture or 1-200 of a grain of strophanthin according to the author.

DR. FRANK WOODBURY read a paper, entitled

A NOTE ON TWO NEW CREOSOTE COMPOUNDS—CREOSOTE VALERIANATE AND GUAIACOL VALERIANATE.

He said that, owing to the fact that commercial creosote is frequently adulterated with coal-tar products, and that, when pure, it contains a variable quantity of guaiacol (sixty to eighty per cent.), efforts had been made to find a substitute. Pure guaiacol is crystalline, but that which is sold under this name is a fluid of pungent, smoky odor, and not well adapted for internal use. Locally, in five-per-cent. solution in sweet oil, as reported by Dr. Newcomb of New York at the recent meeting of the American Laryngological Association, strophanthus acts as an anesthetic when locally applied to the mucous membrane of the nose, and, being free from after effects, is a good substitute for cocain. The reporter had used guaiacol valerianate, applied pure or diluted, and had found it to exert decided analgesic effects. If taken internally, both guaiacol valerianate and creasote valerianate are powerful antiseptics. Being excreted by the bronchial mucous membrane, they exert a local astringent and antiseptic action reducing bronchorrhea. In the stomach these agents are usually well borne and act as antiferments. The combined sedative and antiseptic effects of local applications are best seen in the nasal chambers, in cases of bacterial infection. In purulent rhinitis, for instance, and in some cases of atrophic rhinitis these applications, after thorough cleansing of the nose, yield very good results. Gastric catarrh is benefited by reduction of fermentation, and also by a local tonic action upon the mucous membrane. In early phthisis, the results have been found very good by Dr. Rieck—the appetite and digestive functions are stimulated, there is diminution of expectoration and of cough, the night sweats disappear, the patients improve in weight.

DR. J. C. HENEMETER of Baltimore read a paper, entitled

THE EXPERIMENTAL BASIS OF THE DIETETIC AND MEDICINAL TREATMENT OF HYPERACIDITY AND GASTRITIS.

A very interesting physiologic description of the minute anatomy of the gastric mucosa and the functions of the oxyntic and parietal or central cells was given. He had found that gastric hyperacidity is due to proliferation of oxyntic cells, which are then thrown off and are to be found in the washings from the stomach. He had found the administration of decided doses of alkalies and the aid to digestion of starchy food offered by the use of taka-diastase to permanently relieve this condition.

The Chairman of the Delegation from the American Pharmaceutical Association read certain questions upon which the opinion of the Section was desired. These are the dismissal from the United States Pharmacopeia of spiritus frumenti, spiritus vini gallici, vinum album and vinum rubrum. Replacement of official wines by vinegars. Dismissal of all tinctures having a fluid extract of the same drug official. Substitution for such tinctures and fluid extracts, a fifty-per-cent. tincture under a distinctive title. Change of formula for Dover's powder back to that of the 1890 United States Pharmacopeia, by using potassium sulphate in place of sugar of milk.

After free discussion, in which Dr. Remington, Mr. Kebler, Dr. Stewart, and others participated, it was decided to approve the change of formula for Dover's powder to the old form previous to 1890, which used potassium sulphate instead of sugar of milk.

FOURTH DAY—JUNE 4TH.

DR. G. V. I. BROWN of Duluth, Minn., read a paper, entitled

PRACTICAL DIFFICULTIES OF PSYCHO-THERAPEUTICS.

One of the principal difficulties is the mental instability of many neurotic or degenerate subjects, and their unwillingness to yield to the hypnotic state.

DR. GEO. W. COX of Chicago read a paper on

STREPTOCOCCIC INFECTION AND MARMOREK'S SERUM,

in which very successful results in cases of suppuration and of erysipelas and puerperal septicemia were obtained by the early use of the serum. Marmorck's serum is always used by hyperdemic injection. In all grave cases, such a puerperal septicemia, and especially if treatment has been considerably delayed, an initial dose of 30 cc. is advised. This may be followed by doses of 10 cc. or 20 cc. every twelve or twenty-four hours, according to symptoms. In ordinary cases of erysipelas the initial dose is 20 cc., and in many instances this is all that may be required. The serum is only applicable to the streptococcic infection, and it therefore follows that early bacteriologic examinations should be made.

DR. DELANO AMES of Baltimore read a very elaborate paper on

THE NATURE OF THE LEUCOCYTOSIS PRODUCED BY NUCLEINIC ACID; A PRELIMINARY EXPERIMENTAL STUDY.

He first briefly referred to the introduction of nuclein as a therapeutic agent, pointing out the fact that its use was based upon its property of increasing the germicidal action of the blood. That the blood possessed definite germicidal power was first pointed out by Nuttall working under Flügge. But to what this power was to be attributed was not definitely known until Vaughan of the University of Michigan, succeeded in isolating from the blood a nuclein which he and others demonstrated to possess definite bactericidal properties.

One of the constant effects of the use of nuclein is the production of an apparent leucocytosis. The most important part of Dr. Ames' paper dealt with the discussion of the nature of leucocytosis. Certain writers have claimed that nuclein and substances acting as it does do not have the power to increase the total number of white blood-corpuscles, but that they so affect the circulation as to cause a determination of the cells to the peripheral vessels. This statement, however, seems to be at variance with the findings of many other observers who have proved definitely that by the use of nuclein the germicidal power of the blood of animals could be very materially heightened. Since the germicidal power of the blood resides in its nuclein and since this substance is produced by the white blood-corpuscles it is difficult to understand how a simple rearrangement of the cells in the circulation could in any way increase the amount of nuclein formed. *A priori* reasoning would lead one to believe rather that by the use of nuclein or allied substances the total number of white blood-corpuscles is increased. Dr. Ames' paper was based upon a series of experiments which were made during the past winter by himself and his assistant, Dr. A. A. Huntley of Baltimore, to determine, if possible, what was the exact effect of nuclein upon the blood. Briefly his results may be summed up as follows:

1. Before the administration of nuclein the counts of the leucocytes showed that the number present in both the peripheral and central circulations was practically the same.

2. That following the administration of hypodermic injections of nuclein solution there was immediately, that is, by the end of five or ten minutes, a very noticeable increase in the total number of leucocytes *in both the peripheral and central circulations.*

3. That at this time the percentage increase was most marked in the young mononuclear forms which, in some instances, rose as high as sixty per cent. of the whole within fifteen minutes, while at the same time the proportion of polymorphonuclear elements was proportionally low.

4. That the longer after the injection of nuclein the greater was the actual increase in the total number of corpuscles per cubic millimeter, and this number seemed to rise steadily *in both the peripheral and central circulations.*

Section on Neurology and Medical Jurisprudence.

Second Day—June 2d.

(Continued from page 759.)

The first paper was by Dr. C. C. Hersman of Pittsburg on

THE MEDICO-LEGAL ASPECT OF CHOREIC INSANITIES.

He related the case of a young girl, just past puberty, of neurotic family and personal history, who accused her school-teacher of assault and rape. The girl confessed to having dreamed the night following the alleged attack that the teacher had ravished her mother. The unfortunate teacher was tried and convicted of an assault with intent to ravish. In the reader's opinion, the young girl had had an erotic dream, which on waking remained as a reality. The girl had confessed to some of her friends that it might "have been all in a dream."

INSANITY AND PULMONARY CONSUMPTION AMONG THE NEGRO POPULATION SINCE THE WAR

was the title of the next paper, by Dr. Thomas J. Mays of Philadelphia.

He said that statistics gathered from the superintendents of southern hospitals for the insane show that both insanity and pulmonary consumption have increased disproportionately among the negroes of that section of our country since the close of the civil war. Thus, according to the United States census, there were in 1860 only 44 insane negroes in the State of Georgia; in 1870, there were 129; in 1880, 411; and in 1890, 910. In North Carolina there were in 1880, 91 colored insane; in 1885, 144; in 1890, 244; in 1895, 307, and in 1896, 370. In Virginia before 1865 there were about 60 insane negroes in the asylums of that State, and now there are over 1000. In the Eastern Hospital for the Colored Insane in North Carolina, consumption caused 14 per cent. of the total number of deaths in 1884, while in 1895 it produced 27 per cent. of all the deaths, and this in spite of a reduced general mortality rate. In the Mississippi Lunatic Asylum from 1892 to 1896, consumption caused 42 per cent. of the total number of deaths among the negroes, or an increase of 22 per cent. over the death-rate from this disease among the white population outside of hospitals for the insane (it, of course, being well known that insanity predisposes to phthisis) if the latter is estimated at 20 per cent. In the Alabama Insane Hospital, during three years and nine months beginning October 1, 1890, there occurred 295 deaths among 1700 white and negro patients. Of the 179 deaths among the white patients, 28 per cent. were due to tuberculosis, and of the 116 deaths among the negroes, 42 per cent. were due to the same disease.

From this and other evidence presented, it is concluded that both of these diseases have disproportionately increased since the war, and that in all probability the causes which led to one also led to the other. The speaker held that the predisposing cause of phthisis resides in a disintegrated nervous system, and cited a number of concurrent authorities, as well as clinical and pathologic data, to prove his position; and, among other conclusions, he drew the following: That both consumption and insanity are closely allied, both in personal and in family history, to idiocy, hysteria, epilepsy, and asthma, and to other diseases of the brain and spinal cord; that they are both produced by syphilis, alcohol, overwork, business vicissitudes, domestic trouble, mental anxiety, grief, disappointment, and excesses of all sorts—in fact, by any agent or influence which vitiates the brain or nervous system; and that those who are confronted by a new and higher civilization, and who are compelled to adjust themselves to these new relations, are excessively liable to fall victims to insanity and pulmonary phthisis.

Viewing the condition of the southern negro from these standpoints, it is perfectly obvious why insanity should necessarily develop, and on no other grounds can we explain why consumption should follow in the wake of insanity. Those who are able to realize all the factors which would be called into activity by the environmental change of the negro after the war could, at the time it was made, have foretold the inevitable results which are now but too plain to every one. It is in part a repetition of what happened, and now happens, to the aborigines of North America, Australia, and New Zealand, who in their unequal warfare with modern civilization have been and are being fast decimated and exterminated by pulmonary phthisis.

Dr. T. D. Crothers of Hartford, Conn., read a paper on

INEBRIETY AND TUBERCULOSIS AS ALLIED DISEASES.

He contended that tuberculosis is of neurotic origin, and he was inclined to look upon inebriety in the same light.

Dr. James Hendrie Lloyd of Philadelphia read a communication on

POST-MORTEM FINDINGS IN A CASE OF TRAUMA OF THE CERVICAL REGION OF THE SPINAL CORD SIMULATING SYRINGOMYELIA.

Dr. Wm. G. Spiller of Philadelphia gave further details as to the case, which seemed to leave room for the theory that the fibers for the transmission of the tactile sense are distinct from the fibers for the transmission of the pain or pathic sense.

MENINGOMYELITIS, WITH SPECIAL REFERENCE TO THE TUBERCULOUS FORM.

Dr. Wm. G. Spiller of Philadelphia read this paper, the last of the afternoon, and it was discussed by Drs. James Hendrie Lloyd of Philadelphia, Charles H. Hughes of St. Louis, Hugh T. Patrick, Lichty, Harold N. Moyer of Chicago, and the author.

Third Day—June 3d.

THE PARALYSES, BY ONE OF THE MANY PARALYTICS,

was the heading of an article by Dr. Samuel Knox Crawford of Chicago. Dr. Crawford said that he had suffered a grave lesion of a part of one hemisphere of his central ganglion, and yet was fully conscious of it all, and able to interpret the nerve disturbance and mental perturbation resulting therefrom, and was capable conversely, of locating the lesion from the distal nerve phenomena. He gave his subjective symptoms, prodromal and during the attack.

The next paper was on

NEURASTHENICA ESSENTIALIS AND NEURASTHENIA SYMPTOMATICA,

by Dr. F. X. Dercum of Philadelphia. The author took the position that true neurasthenia is a fatigue neurosis; if the fatigue symptom is not present, neurasthenia is not the proper diagnosis. All the other symptoms of neurasthenia are secondary to this, and may exist in a number of other conditions.

Dr. G. Betton Massey of Philadelphia presented in this connection a communication on

NEURASTHENIA, AN ABDOMINAL NEUROSIS,

advancing the hypothesis that the sympathetic nerve-failure of neurasthenia is due to a retraction of the neuronic processes of certain neurons of the visceral ganglia, thus breaking the circuit of the transmission of secretory energy to the visceral end organs. Auto-intoxication, as explained by Bouchard, seems to furnish an adequate explanation of the mental symptoms of neurasthenia as a simple beclouding of the normal physiologic action of the brain by poisonous elements in the blood.

THE INFLUENCE OF HYPNOTIC SUGGESTION UPON PHYSIOLOGIC PROCESSES,

was the title of a paper read by Dr. R. Osgood Mason of New York. He related a number of very wonderful cures, including relief from constipation, suppressed and difficult menstruation, etc., by hypnotism, and strongly advocated the use of suggestion in proper cases.

Dr. U. O. B. Wingate of Milwaukee, Wis., in a paper on

HYPNOTISM IN THE TREATMENT OF DISEASE,

took a decidedly negative position. He thought that hypnotism should be used guardedly, if at all, and that it will be found that unhappy results follow the frequent hypnotizing of one patient.

THE REST CURE

was the title of the next paper, by Dr. Landon Carter Gray of New York. He thinks that neither electricity nor massage is an essential part of the treatment. He is in the habit of keeping patients in bed not more than two or three weeks, and then gradually allows them to move about. He thinks that there are cases which do not do well under the rest cure, although this discovery of Weir Mitchell's was a wonderful and meritorious one.

REST AND NORTHERN LAKE AIR FOR NEUROTICS,

by Dr. E. S. Pettyjohn, of Alma, Mich., was read by title.

RUMINATION IN MAN

was the title of the next paper, by Dr. Wharton Sinkler of Philadelphia. He gave several instances of this interesting malady.

THE TREATMENT OF GRAVES' DISEASE

was the last subject before the meeting. Dr. Harold N. Moyer of Chicago spoke of the tendency to spontaneous remission in this disease, and the treatment of acute exacerbations by means of strophanthus, also local treatment by an ice-bag over the precordial region, as well as the electric current. The results of his treatment he found were not always satisfactory, in that a permanent cure was difficult, if not impossible.

Dr. Augustus A. Eshner of Philadelphia opened the discussion of the paper. He was followed by Dr. Hughes, who reported better results from treatment, and considered the difficulty due to trouble in the floor of the fourth ventricle associated with the vagus and disordered vasomotor system.

DR. MOYER stated that he had derived benefit from the use of thymus extract.

FOURTH DAY—JUNE 4TH.

DR. CHARLES K. MILLS and DR. MARY ALICE SCHIVELY of Philadelphia presented a paper on

TUMOR OF THE SPINAL MENINGES.

The patient had sweating of one-half of the upper part of the body, radiating pains, and peculiar sensory and motor phenomena. The tumor was found to involve the spinal dura, being situated at about the first or second thoracic vertebra. This tumor had pressed upon the spinal cord, and had pushed the cord in front of it; but the interesting part of the case was that the tumor could have been removed by operation, because most of the spinal cord was intact.

A CLINICAL AND PATHOLOGIC REPORT OF A CASE OF CHRONIC PROGRESSIVE NONSPECIFIC DEMENTIA, WITH ARTERIOSCLEROSIS,

was the title of another paper by DRS. MILLS and SCHIVELY.

TUMORS OF THE CEREBELLUM, WITH A REPORT OF A CASE

by DR. A. O. J. KELLY of Philadelphia was read by title.

DR. JOHN K. MITCHELL of Philadelphia presented an interesting

CONTRIBUTION TO THE PATHOLOGY OF MYELITIS, ACUTE AND CHRONIC,

and DR. JOHN H. W. RHEIN read a paper on

LESIONS OF THE SPINAL CORD DUE TO TUBERCULOUS DISEASE OF THE COLUMN, WITH MICROSCOPIC SPECIMENS.

DR. HUGH T. PATRICK of Chicago referred to the retention of the reflexes in some of these cases. He spoke of a case of Potts' disease in which the knee-jerks were lost and then returned.

DR. HERSMAN of Pittsburg put in a plea for the use of the anatomic designations of the different portions of the system, rather than the names of the discoverer of the part.

DR. DERCUM referred to a case of locomotor ataxia in which the typical condrome was present, the knee-jerks being absent. Apoplexy occurred, with an apparent hemorrhage, and the knee-jerks returned on the paralyzed side.

DR. HUGHES thought it was undoubtedly a fact that the reflexes do disappear and return.

TREMOR IN CHOREA,

was the title of a paper by DR. JOHN H. W. RHEIN.

DR. CHARLES H. HUGHES of St. Louis, the new Chairman, was then conducted to the Chair by Dr. Dercum of Philadelphia, and Dr. Pettyjohn of Alma, Mich. Dr. Herdman, the retiring Chairman, made some appropriate remarks, and Dr. Hughes thanked the Section for honor conferred upon him.

DR. PETTYJOHN then presented resolutions thanking Dr. Charles K. Mills, the Philadelphia Neuralogical Society, and the neurologists of Philadelphia, for their indefatigable efforts to contribute to the success of the meeting and their consideration of the comfort and enjoyment of visiting members.

REVIEWS.

A TREATISE ON SURGERY. By American Authors. Edited by ROSWELL PARK, M.D., Professor of Surgery and Clinical Surgery in the Medical Department of the University of Buffalo. Vol. II., Special Surgery. Philadelphia and New York: Lea Brothers & Co. 1897.

THE reputation already gained for Dr. Park's "Surgery" will certainly not be diminished by the appearance of the second and concluding volume. Success was already assured and this volume will undoubtedly increase the popularity of the work. Volume II. is devoted to "Special and Regional Surgery," and is divided into twenty chapters. It opens with an admirable chapter by the editor on the "Injuries and Diseases of the Head." He describes briefly but well the affections of scalp and bones. In the treatment of head injuries many of the old rules and precautions are wisely ignored, and in their place are substituted practical modern views, as in cases of fracture, "in every case of doubt it will be wise to make exploratory incisions," "whether the fracture be compound or not, calls always for operation," etc. He properly restricts the term concussion to cases of shock following injury, and gives no parallel columns to puzzle the practitioner as to whether the case be one of concussion or compression. He gives a judicial view of the surgical treatment of epilepsy, not too enthusiastic. His memoranda of cranial topography is useful, and the description of operative technic, explicit and correct. His opinions throughout are clearly and decidedly expressed.

Chapter II. treats of "Injuries and Surgical Diseases of the Spine," by E. H. Bradford. The different subjects are well discussed. His position in regard to operations for fractured spine is sufficiently bold, and at the same time conservative. The surgery of the peripheral nervous system is also briefly considered.

In Chapter III. the "Surgical Diseases of the Heart, Pericardium, and large Blood-vessels" are clearly described by Duncan Eve. Twenty-four pages only are devoted to ligation of arteries, an improvement, certainly, on the lengthy descriptions in the older surgeries, but even yet too lengthy.

In Chapter IV. a good account is given by Bryson Delavan of the "Surgical Diseases and Injuries of the Respiratory Organs." Too much space, however, is devoted to minor affections and their treatment, and not enough to the operations which more properly come within the scope of the general surgeons; for example, the external operations for nasal and pharyngeal growths.

Chapter V. treats of the "Surgical Diseases and Injuries of the Face," by Edmond Souchon, and in Chapter V. (continued), the second section, of the neck. The various affections and operations are *clearly* but *briefly* described. The heading "Congenital Malformations" seems to include gunshot wounds, gangrene, etc., etc. In the treatment of deep abscesses of the neck too much importance is given to the so-called "guided dilatation," and too little to a clean and open incision.

Chapter VI. deals with the "Surgery of the Chest," and the author is Frederic S. Dennis. It contains an excellent paragraph on subphrenic abscess. The descriptions of the various surgical affections and operations are clear and concise.

In Chapter VII. "Diseases and Injuries of the Mouth, Tongue, and Jaws" are discussed by Arthur D. Bevan. This is a clear and well-written chapter. In an "Appendix," by T. W. Brophy, on early operation for cleft palate are given plausible reasons for surgical interference in early infancy, and descriptions of rather novel methods.

In Chapter VIII. the "Surgery of the Abdomen" is treated in a masterly way by Maurice H. Richardson, assisted by Farrar Cobb. The chapter contains a great mass of solid information, expressed in a clear and concise manner. His statements are explicit; as, "a gunshot wound of the abdomen, when seen directly after infliction or within an hour or so, demands immediate investigation, whatever the symptoms," etc. His treatment of appendicitis is judicious; "in cases of doubt it is safer to operate than to delay." His description of McBurney's intermuscular operation lacks clearness.

In the next chapter "Hernia" is discussed by the same author. The article is not overburdened with descriptions of useless operations. Bassini's and Halsted's are wisely chosen as the best, and these alone are described. He speaks of the dangers of "taxis," but might have laid more emphasis on this subject.

The next chapter, by Charles B. Kelsey, is an excellent one on the "Rectum and Sigmoid Flexure." There are many instructive illustrations. In discussing fistula, he says: "In these operations it is well to bear in mind that a large percentage of all cases are failures, even in hospital practice," a fact which is certainly true, but is not generally appreciated. He gives a hard blow to the old theory that all strictures which are not malignant must be syphilitic. "There is, I think, no rarer lesion of the rectum than a syphilitic stricture."

Chapter XI. treats of "Genito-Urinary Surgery," and the subject is well handled by Wm. T. Belfield, though, owing to the limited space, it must naturally be too condensed. Consequently internal urethrotomy and some of the surgical kidney diseases are rather slighted.

The next chapter, a brief one, is by the editor on "Chancroid or Venereal Ulcer."

Chapter XIII. is devoted to the "Female Reproductive Organs," and is written by James H. Etheridge. He gives a full and clear description of the various minor diseases and operations, as perineorrhaphy, Alexander's operation, etc. Many excellent plates add to the clearness of his descriptions. The major operations are described with less detail, but with equal clearness.

The "Diseases and Injuries of the Breast," are treated in the next chapter in a most admirable manner by Charles B. Parker.

Chapter XV., on "Amputations," is written by Rudolph Matas. The descriptions of the various methods are clear and sufficiently detailed. To F. Tilden Brown, instead of Dillon Brown, should be given the credit of a most excellent method for hip-joint amputations.

The next chapter, by Robert W. Lovett, deals with "Orthopedic Surgery." It is clearly written, and contains excellent illustrations of deformities and appliances. He considers operations for congenital dislocation of the hip as still *subjudice*.

In the following chapter a graphic account of "Plastic Surgery" is given by Arpad G. Gerster. There are many diagrams which illustrate the various methods better than words.

Chapter XVIII. is devoted to the "Eye and Orbit." It is comprehensive and well written, but it seems unfortunate that part of the forty-eight pages should not have been assigned to some other subject of more importance to the general practitioner and surgeon.

The next chapter is written by Clarence J. Blake on the "Injuries and Diseases of the Ear." It gives a satisfactory account of all that the general surgeon need know on this subject. In describing mastoid operations, several of the lines devoted to the external incision might better have been devoted to indicating the dangers to nerve and sinus which this delicate operation entails.

The volume closes with a brief account of "Skiagraphy," by the editor.

Dr. Park and his associates are certainly to be congratulated on the admirable work which they have given to the profession. For the student, general practitioner, and surgeon this is a most satisfactory "Surgery." In two volumes are condensed as much valuable information as is contained in other treatises of double the size. Obsolete theories and operations are not even mentioned, and the modern scientific spirit pervades every chapter of the book. Its general excellency and consistency is most praiseworthy, considering the large number of authors. It is well written throughout, clear, and condensed. It is comprehensive and yet not too elaborate. It will be an interesting and instructive text-book for the medical student. The practitioner can refer to it and be assured that here he will find the most approved and modern views on all surgical subjects.

The work has rapidly sprung into favor, and it is already deservedly known as our best text-book on surgery.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NORTH CAROLINA. Forty-third Annual Meeting.

BESIDES the address of the president, Dr. R. L. Payne, this volume contains a number of readable and valuable articles. Among them may be mentioned "Management and Treatment of Tuberculosis in the Asheville Climate," by Dr. J. A. Burroughs;" "Something of Surgical Tuberculosis," by Dr. J. L. Nicholson; "Serum Therapy," by Dr. W. O. Spencer, and "Is there in North Carolina a Continued Fever which is Neither Typhoid nor Malarial?" by Dr. H. A. Royster.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, JUNE 19, 1897. NO. 25.

ORIGINAL ARTICLES.

ERYTHROMELALGIA ASSOCIATED WITH RAYNAUD'S DISEASE.

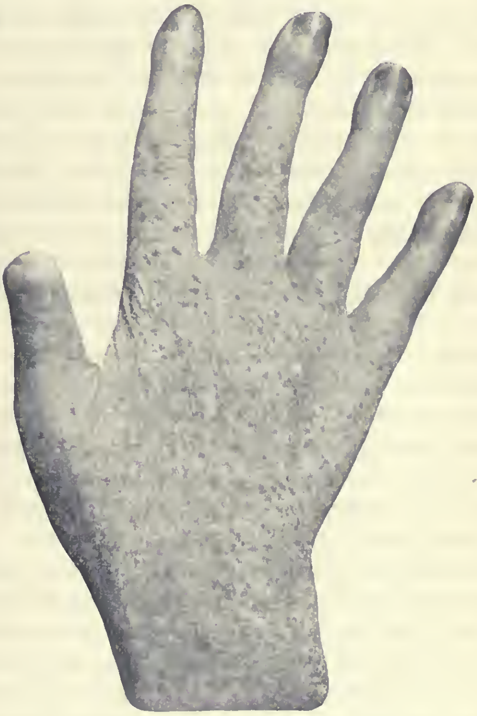
BY HENRY L. ELSNER, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF THE SCIENCE AND ART OF MEDICINE AND OF CLINICAL MEDICINE, SYRACUSE MEDICAL COLLEGE.

ON the 28th of October, 1895, I was called in consultation with Dr. Monroe to see Mrs. H., aged thirty-eight, the wife of a coachman, living in a poorly ventilated house with unfavorable surroundings. The patient's family history presented nothing noteworthy. Her parents were dead, but had reached old age; her brothers and sisters were living and well. She had given birth to three children, and had had one miscarriage. Two of the children are living and enjoying good health. One daughter died at the age of thirteen years of diabetes. The patient had always been a hard-working woman, having done all her own work, including large washings during the summer and winter months. During the winter, she suffered greatly from exposure, due to her impoverished circumstances and environment.

Until February, 1893, she had enjoyed perfect health. She denied specific disease. Her usual weight was over two hundred pounds. She had already lost considerable flesh when I was called to see her. Menstruation was established at thirteen. It had never been markedly abnornal, but of late had been somewhat scanty. She had never suffered from disease of the nervous system, and was not considered neurotic or hysteric by her attending physician, who had seen her at short intervals during the preceding month. Her present illness dates back to the winter of 1893, when she commenced to suffer from severe headaches, mainly frontal, though at times occipital, which were almost always associated with a sense of fulness in the head, and with more or less flushing of the face. It was for the relief of this symptom, which had become alarming and painful, that I was called to see her. In connection with the headaches, she occasionally had been annoyed, during the extreme hot and cold weather of 1894–5, by a burning sensation in the palms and backs of both hands.

The volar surfaces of the fingers of the right hand were most painful from the beginning, and at this time, as well as during the subsequent course of the disease, became the seat of the most intense suffering and greatest pathologic change. During the early months of the disease, and until February 5, 1896, when I was again called to attend her, the pains were paroxysmal, and were always associated with a maculo-papular erythema of an evanescent character, which disappeared with the burning and with the pain. These eruptions were accompanied finally by the severe headaches already mentioned, until the middle of February, when the latter ceased, and have never recurred. Early during February, the left hand showed a few spots of erythema, and was painful to pressure only, while the right hand, by the end of February, was studded with characteristic shot-like papules of erythema over the palm at numerous points, some reaching above the wrist. These papules were exquisitely tender, and were associated with continuous burning, stinging, and throbbing, making it impossible for the woman to use her hand, to bear anything upon it, or to move it without suffering untold agony. There were no symptoms referable to the left hand after March, 1896. After

FIG. 1.



Right hand, showing persistent papular eruption.

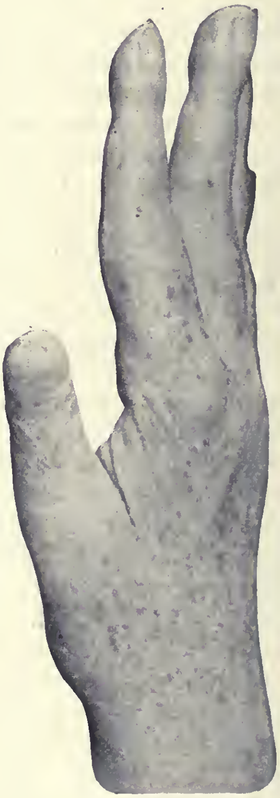
this date the erythema and pain became continuous in the right hand.

Now commenced a period of torture and continued suffering which has never been equalled by any experience which I have had with peripheral pain. The words of Musser are true, when, in speaking of the condition present in this disease, he says: "I know of no peripheral pain which is the cause of greater agony." Erythematous spots were continually present, sometimes as many as eight or ten on each finger, with a reddened area surrounding the nails. These papules during the acute exacerbation were tense, shining, and so exquisitely tender that the hand could not be rested even on a soft pillow, but was constantly held quiet, while firm pressure was made with the left hand above the wrist to prevent sudden movements and jerkings of the fingers during the paroxysm of darting pains and transmission of movement from the body. The patient was unable to sleep or eat more than was sufficient to keep her from starvation.

Bemoaning her fate with tears in her eyes, she came to me frequently begging for relief, and in her agony suggested her willingness to have the hand amputated rather than continue in her misery. She could explain her sufferings only by repeating day after day that "she felt as if her hand was being consumed by a living fire, and that hundreds of pins were being pricked into each tender spot." At times there were sudden darting or shooting pains into the fingers to the tips. The hand, wherever the spots were present, both on the palmar and dorsal surface, was covered with thousands of sweat drops during the more severe pains, and after prolonged pain the epidermis was sometimes loosened. At times the smaller papules were found in clusters, and occasionally became confluent to form the larger and more tense patches which, as they disappeared, left no vestige of their original seat save for about twenty-four hours, when a small nodule could be felt under the skin, less tender than during its blushing period. Never was there evidence of hemorrhage in purpuric spots, or of ultimate ecchymosis. As already stated, at this period the hand was never without some papules, and the lesions about the finger tips were continuous, their brightness and tension varying, being most intense and severe during the frequent acute exacerbations of her subjective symptoms.

From March, 1896, until about the fifth of September, there was no material change in the condition of the patient. All movement of the right hand and arm was limited owing to the persistence of her symptoms, and a moderate atrophy of tissue resulted. In the fingers there were trophic changes; they seemed elongated and spindle-shaped, and somewhat stiff. The radial pulse was the same at both wrists. An examination showed the right hand to be hypersensitive (hyperalgesic). Touching any erythematous patch with the estheiometer caused pain to continue for some minutes after contact. Tactile sense was somewhat tardy, but not materially changed. There were no changes in cutaneous sensibility in the normal skin of the diseased hand, nor in that of other parts of the body. Reactions to both the faradic and constant current were normal in all the hand and arm muscles. There was absolutely no reaction of degeneration in the smaller muscles of the hand.

Fig. 2.



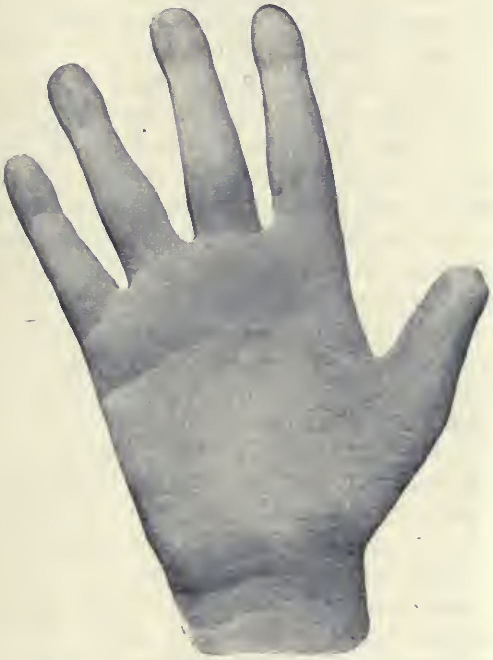
Profile view of right hand, showing position of fingers.

It was discovered that for years the patient had suffered from cystocele, uterine prolapse, and rectocele, which conditions were associated with a urine of normal specific gravity containing a trace of albumin, bladder epithelium, bacteria, and pus. This in all probability was aggravated by the constant pressure of residual urine due to the bladder prolapse.

During all these months treatment availed but little. The writer went through the grand galaxy of remedies usually recommended for the relief of peripheral pain, with indifferent results. The iodids and mercurials were given a fair trial and were found insufficient to control the disease. Electricity even in small dosage increased the pain. Opium and morphin were never given, as the diagnosis presupposed an unfavorable prognosis; chronicity was expected and I feared the formation of the opium habit. Occasionlly it was imagined that salipyrin, antipyrin, and acetanilid, caused slight relief.

One of the most interesting of the many phenomena which I noticed in this case occurred on September 12, 1896. The patient came to my office for the purpose of having another drawing made. The hand, with the exception of the thumb, presented about the usual appearance and was equally troublesome. It was noticed that the thumb was more deeply colored than usual below the terminal phalanx, while the tip was a brighter red than ever before. The deep congestion suddenly faded, the entire finger assuming its former color. This evanescence was sudden and decided.

Fig. 3.



Palmar surface of the hand, showing the smooth stump after complete amputation of the thumb by dry gangrene. Different views of the stump are given in Figs. 1 and 2.

During August it was noticed that there were several erythematous spots, varying in size from a pinhead to a split pea, on the left cheek, and one large papule on the left tragus. While these were less sensitive than those on the hand, their advent was associated with considerable suffering along the branches of the infra-orbital nerve, and persisting, they become more and more tender to pressure. They were bright red, hard, and became pale on pressure. The larger papules, more particularly that on the tragus, added to the discomfort of the patient by a constant burning which became more annoying as it became more tense.

About the end of the first month of this eruption, the erythema gave way to a characteristic blueness, and the pain grew less; finally, all the original spots of erythema became gangrenous and sloughed. The deepest slough came from the tragus, and in about eight weeks from the beginning of the facial erythema this process had run its course. The gangrene was followed by repair, and the pain in the face and ear was relieved. The only other superficial loss of tissue noted in this case followed an erythematous spot about the size of a three-cent piece over the middle and at the free margin of the left sternocleidomastoid muscle. This behaved much like the facial gangrene, was not as deep as that on the left tragus, and healed without treatment.

This brings us to the more important and unique complication of this rare symptom complex. The striking bright color of the end of the thumb has already been mentioned. There was no coldness anywhere about the fingers, there had been no change in symptoms, and the case seemed as hopeless as ever before. On the 16th of September there were positive evidences of gangrene of the terminal phalanx of the heretofore erythematous thumb. The tip became cold, blue, shriveled in appearance, and had a distinct V-shaped line of demarcation. After a process of dry gangrene it separated entirely on October 21st, leaving the articular surface of the bone below clean and smooth. In another month this had completely healed.

A word concerning the behavior of the erythema and pain after the beginning of the gangrenous process: While the erythema was by no means controlled, but few new papules appeared; these were less painful, lasted a shorter time, and their disappearance was followed by less subcutaneous infiltration than had been experienced during the active period of the disease. These were erythematous at all times and presented the same appearance as those which preceded the gangrene. The macular erythema surrounding the finger tips did not fade until the disease had run its course. The burning, stinging, and darting pain became less, was more easily endured, and ceased entirely after the separation of the finger tip on October 21st. Shortly after this occurrence there were no symptoms referable to the hand though the trophic changes are seen in the fingers. These continue somewhat stiff. The muscles have not yet fully regained their normal development. The photographs kindly taken by Mr. Van Duyn show the condition of the hand at the present time. There is no sign of erythema. Since her recovery the patient has successfully withstood an alarming attack of pneumonia.

The history of the case justifies the diagnosis of *erythromelalgia associated with true Raynaud's disease.*

In 1872 a paper was written by Weir Mitchell[1] describing a peculiar condition in which a foot or hand (usually a foot) became red and at the same time painful, without attending phlegmon or inflammatory changes. But little notice was taken by the profession of this communication until the same author, in July, 1878, in an article "On a Rare Vasomotor Neurosis of the Extremities, and on the Maladies with which it May Be Confounded," [2] reported fifteen cases of the disease, which he elaborated in his usually graphic style. He suggested the propriety of "labeling" the condition associated with erythema and pain in the extremities "erythromelalgia."

In the preparation of this paper the writer has searched all available literature on the subject at his command, and appends a bibliography which, if studied, will be found to give reference to forty-four cases, including the one above detailed. In this search it was discovered that the acute observer and clinician, Graves,[3] in 1843, described a peculiar condition of the extremities associated with symptoms much like those mentioned later by Mitchell, in which he suggested that the nerves and arteries of a part independent of the heart could affect local circulation sufficiently to give rise to local symptoms of a peculiar and unique character. In spite of the detailed description of erythromelalgia given by Mitchell, but few cases of this condition (Grenier,[4] 1873, Sigerson and Vulpian[5] 1873) were reported for a number of years, and these without reference to the original articles. So rarely was the disease mentioned in medical literature that the writer finds no reference to erythromelalgia in the Index Catalogue of the Library of the Surgeon-General's Office. Until 1892 the only case mentioned in German medical literature is found in the work of Seeligmuller[6] on "The Diseases of the Nervous System."

Lannois,[7] in 1880, in a thesis on this subject, could find but twenty-four cases to report, including those of Weir Mitchell, with others,[5] which were positive and two or three which were doubtful.

An interesting coincidence was the presentation of three cases of this affection at a meeting of the *Gesellschaft der Charite-Aerzte* by Gerhardt,[8] Senator[9] and Bernhardt,[10] after which a thorough discussion followed, and several present mentioned conditions met in practice resembling very closely the cases reported. These articles are cited in the appended bibliography.

From 1880 to 1892 Senator in his search could find but four new cases. Besides the references already given, the writer found the subject most thoroughly considered in the *Encyclopadische Jahrbucher*[11] of 1893–1894; while the most exhaustive article which has thus far appeared is found in the *Berliner Klinische Wochenschrift* by Lewin and Benda.[12] The latest, and one of the most scientific considerations of erythromelalgia yet published, is given by Dehio[13]. These with many others of great value and interest are cited in the bibliography which accompanies this paper.

The clinical history of the case reported is full of interest, not so much because of the fact that it pictures a case of erythromelalgia, but for the reason that it proves beyond question the fact that Raynaud's disease may accompany this condition, a complication which has been denied heretofore by some writers on this subject.

In Collins' article, which appeared in Dercum's work on "Nervous Diseases," the positive statement is made—in considering the diagnosis of Raynaud's disease—that "Erythromelalgia may be confounded with Raynaud's disease when local erythema occurs in the second stage, but it may be differentiated by its mode of onset and the fact that erythromelalgia never goes on to gangrene."

After giving Dr. Collins a brief history of my case he kindly wrote, that "from the data which I have at hand, I have never seen a case of erythromelalgia associated with or followed by gangrene, and I have had occasion to see many of these cases during the past few years." He said, further, "It seems to me that in your case there is no doubt that the gangrenous process has followed on the symptom complex constituting erythrymelalgia. . . . I shall keep your case in mind when I correct my article for the next edition."

The writer's case stands practically alone in medical literature so far as he has been able to discover, for no case has come under his notice in which the last stage of Raynaud's disease accompanied erythromelalgia. I have found but three references which bear *directly* upon this phase of the disease. Morell-Lavalle[14] reported a case in which the symptoms of erythromelalgia alternated with those of partial local syncope. The second case is reported by Mills[15], in which the patient, a woman aged twenty-three years, after two years of persistent erythema of the extremities, developed symptoms resembling the milder Raynaud phenomena.

The third case—that of Dehio[13]—was treated November 28, 1894, by resection of a small portion of the ulnar nerve above the wrist, and an equally small piece of the ulnar artery. During the following

April (1895) the tip of the little finger of the operated hand became black and a small piece of bone with pus and blood escaped.

The propriety of changing the diagnosis to Raynaud's disease after the advent of gangrene was naturally considered. The unusual length of time during which the erythromelalgic symptoms continued, with their persistence after the fully developed gangrene, led me to conclude that the latter was a complication depending upon the former; hence I preferred to continue the diagnosis of erythromelalgia and speak of the Raynaud's disease as an accompaniment and sequel.

The question of the true pathology of the subject under consideration has never been settled. Erythromelalgia is conceded by almost all authorities to be a condition depending upon vasomotor disturbance. Whether it ought to be considered an independent disease is by no means decided, though Dehio believed that his case justified that conclusion. We are not ready to assert with any degree of certainty that it is always dependent upon the same pathologic change. Until our knowledge is enriched by positive pathologic data, we are safe in considering the symptom complex, dependent on either peripheral, cerebral, or spinal changes, particularly involving the cervical and lumbar portions of the cord, most likely the posterior and anterior horns of the gray matter. That a close relation exists between erythromelalgia and Raynaud's disease there can be no doubt when the symptoms of the reported case and those to which I have referred are considered (Osler[16]). The early headache, the erythema, the pain, and the final gangrene, were dependent upon the same underlying cause.

Dehio's case, already mentioned, is the only one on record in which an examination has been made of the artery leading to the diseased area. Microscopic section showed marked changes in the intima, which materially narrowed the lumen of the vessel.

The ultimate gangrene in my case can be explained in no other way than by considering it the result of secondary vascular change, a conclusion which is strengthened by the overwhelming evidence of changes in the arteries, particularly in the intima, consequent upon long-continued distension or vasomotor paralysis. Thoma,[17] in his brilliant and convincing article which appeared in Virchow's *Archiv*, established the fact beyond contradiction that compensatory changes take place in arteries which have remained distended for a considerable time, and which in truth are too large for the blood which courses through them. In my case it is safe to conclude that this compensatory effort finally caused complete occlusion in some of the smaller arteries supplying the terminal phalanx of the thumb, and death of the part resulted.

Factory Inspection in Newark.—Chief Factory Inspector of New Jersey John C. Ward is making the rounds of the bakeries and factories in Newark and Essex County. So far no violations of law have been found. Child labor is still in evidence, but largely through evasions of the law by parents. Children are required to have certificates before they are employed. The old unsanitary condition of bakeries has been abolished by the law. The baking in all places is done in well-ventilated, clean rooms. The improvement noticed is due to rigid enforcement of the law, which resulted in the successful prosecution of several violators.

DIAGNOSTIC AND THERAPEUTIC CONSIDERATIONS WITH RESPECT TO CERTAIN DISEASES OF THE UPPER AIR-TRACT.[1]

By BEVERLEY ROBINSON, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO ST. LUKE'S HOSPITAL.

I FEEL quite sure that none of those who are present will be inclined to question the great advances which have been made during the past twenty years or more in the diagnosis and treatment of many affections of the upper air-tract. Thanks to the use of the laryngoscope and rhinoscope, we have before our eyes the diseased appearances of the throat and nose. Taken with the functional disturbances which accompany them in greater or less degree, and with microscopic investigation, frequently of diseased tissues which may be and are properly removed at times by surgical means, a very accurate statement can be made of the nature of the lesion. Whenever, for sufficient reason, pathologic examination cannot be made during life, as, for example, when no operative procedure has been instituted, and if death occurs later, investigation enables us to define closely the diseased process.

While the foregoing will doubtless be admitted, the other side is surely true, *viz.*, that with the greater insight into certain conditions which at first appear to be local in their origin and march, the constitutional influence is apt to be ignored in a measure, and the symptoms in the main are accounted for too much by mere local changes. Thus it has become true that local applications, operations, various, simple, or difficult, are believed to ameliorate or cure, and the general system is comparatively little if at all considered or attended to. It has seemed to me that the later German school of medicine is largely responsible for the somewhat narrow and unfortunate interpretation of diseases of the upper respiratory tract. General applications of disease—general pathology—the philosophic combining of many local expressions of impaired function under one head—that, has been, in my judgment, the work of the French school. With them it is not new. It goes back far. It began, indeed, with Broussais, was carried on by Bouillaud, Trousseau, Grisolle, and those of our own day and time, and still remains. There is a *juste milieu*, or happy medium, and this is the true goal of the diligent worker, the careful observer, the searcher after truth.

Ten or fifteen years ago every well-educated physician who had given even limited attention to the study of nasal or throat affections provided himself with a suitable atomizing apparatus, and was convinced that by frequent applications of a spray, astringent or soothing in nature, he could effectually allay many inflammatory affections. Even at that time internal medication of the upper respiratory tract was considered to be of secondary importance by very many men, skilled and learned in their art. By and by they found that these inflammatory conditions were not always relieved or cured after this manner, and they quickly sought the solution of the problem. In the nose, it was affirmed, hypertrophy of the turbinates, or a deviated septum, existed, and these were the underlying pathologic conditions which occasioned repeated acute inflammation locally.

When this opinion was firmly established we know how soon the period came when frequent operations on the offending structures were performed. The turbinates were cauterized, chiseled, trephined, excised. Numerous ingenious devices rapidly accumulated for straightening the septum, for excision of redundant tissue, for planing down all bulging or irregularities. Despite all this doing, and the rapid increase of the specialists in diseases of the throat and nose, it was found that nasal and throat affections were none the less prevalent. To-day I am happy to say there is a manifest tendency on the part of a few to acknowledge the governing forces in the human economy. These physicians recognize at present that a septum is often irregular and deviated among perfectly healthy individuals; they know that the better way of keeping down a growing hypertrophy of the soft tissues over the turbinates is to give mild aperients to act on the liver, to treat with appropriate, general means every acute coryza which develops, and not let it run its course unchecked. They know that the gouty, rheumatic, lithemic, malarial, syphilitic dyscrasiæ will excite and produce inflammatory action of the pituitary membrane despite the most careful hygiene, unless wise indications of treatment are carried out carefully and intelligently. Nor is this all. They know that fatigue, bad air, damp, changeable atmospheric conditions will also promote these manifestations; and yet they also recognize that there are times when a conservative local treatment, or well-considered operation, is the only satisfactory method of securing good results.

Again, some of my *confrères*—the specialists—know at present that when a surgical procedure is adopted, in order to be successful attention should be paid to surgical methods; and by this I do not mean merely to understand what operation should be done, and to have the skill and courage to perform it; but they must also have the means and opportunity and knowledge to treat the patient's nose with aseptic precautions before, during, and after the operation. In this way, and this way alone, are many operations justified by the ultimate benefit which the patient receives. It behoves the general practitioner to recognize when and where he can acquit himself properly and conscientiously. In order to know this much it is not essential to be a specialist of nasal and throat affections. It is necessary, however, to acquire moderate skill in the use of the rhinoscope and laryngoscope, and afterward to make use personally of the correct treatment or pass the case over for awhile, at least, to one who has sufficient knowledge and conscience to treat it properly.

---

[1] Read at the Twelfth Annual Meeting of the Association of American Physicians, Washington, D. C., May 5, 1897.

Take, for example, a very large number of persons who have a so-called nasal catarrh. They may be adults or children, and the condition may be marked by obstruction of the nasal passages, which is carried to that degree, very often, that they become more or less habitual mouth-breathers. Some there are in whom the mouth-breathing occurs only at times, and during or subsequent to an attack of coryza; others there are who for many weeks or months, and especially at night, in the recumbent posture, cannot get air enough through the nasal passages. Very many cases of both types can be completely relieved by one or more mild cauterizations with glacial acetic acid. This acid is rapidly and efficiently applied to the nasal mucous membrane by means of a flattened probe wrapped in cotton. A two-per-cent. solution of cocain is sprayed into the nasal passages a few moments previous to the application of the acid, and all pain is abolished. The nares are covered with a little vaselin in advance, and all risk of irritating the skin is avoided. An antiseptic spray through the nasal passages after the cauterization, and the use of a borated cotton plug in the nares for a few hours, takes away the bare possibility of any subsequent complication. In a few days the patient blows into his handkerchief a few shreds of mucous membrane, white in color, and great, if not absolute, relief of breathing quickly follows.

Another symptom of a very frequent ailment in adults and children, with or without nasal obstruction, is the frequent dropping of mucus or muco-pus from the nasopharynx into the throat. It occasions cough, bad breath, and disordered digestion. To men and women it is a source of extreme annoyance, and even disgust, from the fact that they are frequently compelled either to swallow this offensive, nauseous secretion or to expel it by efforts of hawking and expectoration. Children are awakened at night with choking attacks, laryngismus, night-terrors, obstructed breathing, thus occasioned. How can it be relieved? By general medication alone? By change of air? By dieting? Very rarely, if ever. Will inhalations or atomized solutions through the nose relieve the condition and obviate the subsequent phenomena? Frequently they ameliorate for awhile; very exceptionally they do more. In adults direct astringent or antiseptic applications to the nasopharynx of tincture of the perchlorid of iron and glycerin, compound tincture of iodin, or of carbolic acid and glycerin will often be of great service in a very short time. To still further augment their value, however, we must often attend to general conditions, and here, again, anemia, impaired nutrition of different causation, the herpetic diathesis, must be taken into account and wisely treated. For many such a sojourn at an alkalin or sulphur spa abroad will help wonderfully to produce a lasting cure.

In children we should constantly bear in mind that such symptoms, if persistent, will often indicate a more or less considerable development of adenoid tissue. Here, again, the local applications before mentioned may prove to be very useful; but if the mass of tissue be at all pronounced, and the child be in relatively poor, general health, they are insufficient. To secure absolute relief we must depend on direct removal of the tissue itself. If the amount be small, it may be removed in many instances with the nail of the index-finger, with is introduced behind and above the palate to scrape the nasopharynx thoroughly. The finger should be protected with a suitable finger-stall in rubber or metal, and the hand washed with soap and water, and bathed with alcohol before its introduction. The child's head is bent forward over a proper receptacle, and after the scraping is finished (which takes only a few moments) the child is urged to blow the resulting blood, mucus, and shreds of adenoid tissue from the nose, and also to expectorate them from the throat.

Frequently such operation as this is insufficient or not indicated, and to establish a complete cure a specialist's operative treatment should be secured. This means preferably the use of Gottstein's curette or of some form of forceps, usually aided by means of more or less profound local or general anesthesia with cocain, nitrous-oxid gas, bromid of ethyl, chloroform, or ether.

The presence of the so-called hypertrophied lingual tonsil or lymphoid tissue, which frequently enlarges in front of the epiglottis in the glosso-epiglottic fossa and encroaches upon the larynx, is often ignored or improperly treated. Many times I have observed cough—irritative, ineffectual, obstinate—thus occasioned. The use of cough-mixtures, inhalations, and sprays, are relatively useless, and even climatic changes, cod-liver oil, etc., are ineffectual to cause notable amelioration in this local state. In many instances, however, this tonsil becomes acutely inflamed and swollen, and when such is the case it is without doubt produced by a rheumatic or gouty dyscrasia. To ignore the use of the salicylates and colchicum means either no cure or surely a very protracted course of treatment.

Whenever the tonsil is chronically enlarged and occasions globus hystericus (so-called) or choking sensations, and a constant tickling and irritation in the throat near the larynx, recourse must be had first to local applications of iodin, carbolic acid, or iron. If these fail, repeated applications of the galvanocautery will ultimately afford permanent relief in many instances. In the most severe cases ablation by means of Chapelle's tonsillotome, or some similar instrument is our sole available and suitable resource. Under these circumstances a specialist's services are usually required.

Take, now, numerous examples of laryngitis, acute, subacute, or chronic in nature. Is there no such disease as an acute inflammation of the larynx? One bold specialist of wide renown has almost dared to affirm it. So convinced are some laryngologists that acute laryngitis proceeds from and is almost wholly caused by inflammation, or obstruction of the nasal passages, that they give the larynx itself little or no treatment—local or general—and yet how erroneous such views are. I am here prepared to affirm, and I still believe, that there is such a disease, and a tolerably frequent one, as acute laryngitis. I believe it may be intercurrent with inflammation of the nose, pharynx, trachea, and bronchi. I believe it may be limited in a great degree to the larynx itself, and in either case be in no sense dependent upon the intranasal condition. I believe, also, that there are numerous instances in which the acute laryngitis is preceded by nasal and pharyngeal inflammation.

In many examples of acute laryngitis I should consider myself derelict in the highest degree if I did not combine general and local medication. When, however, we come to the treatment of the subacute form of laryngitis of simple catarrhal or inflammatory type, I rely mainly upon the use of local applications of iron, iodin, zinc, copper, and carbolic acid, aided with mild antiseptic sprays. If the catarrhal condition continues or extends to the trachea or bronchial tubes, I feel called upon to make appeal to anticatarrhal agents internally, among which I rank ipecac, ammonia salts, and beechwood creosote highest.

If the laryngitis be chronic, and either the syphilitic or tuberculous nature of it be suspected or confirmed, we must combine appropriate local and general means to attain the best results of treatment. In order to follow up such cases intelligently and judiciously we should make frequent, skilful use of the laryngeal mirror and the armamentarium of the well-informed laryngologist.

Is it wisdom to inject the soft parts with antiseptic preparations or scrape out ulcerated tissues and apply painful caustics in order to effect beneficial local changes, if possible, of laryngeal tuberculosis? I believe not, in the large majority of cases.

My conviction in this matter exists because, as a rule, the concomitant intrapulmonary condition is of such a character—of such an advanced stage of tuberculization—that I regard it as almost criminal to make a poor sufferer submit to additional pain for a prospective gain of little or no value. Still, there are a few exceptions to this rule. Krause and Heryng have reported, as we know, some very brilliant results from active local interference, and he would be an ignorant or unwise practitioner wholly to disregard them in all cases.

In syphilitic stricture or stenosis of the larynx or nasopharynx it is not broad-minded to ignore what intubation or palliative dilatation may be able to accomplish in any way of relieving constant distress. Here, again, the specialist has his *rôle*, and a valuable one it is, to help us ameliorate otherwise hopeless cases.

I might prolong this paper unduly. I have written sufficient, I trust, to open a fruitful and interesting discussion of a practical and important subject. In no branch of medicine are the contrasts more frequent and essential between the general practitioner and the specialist than in what pertains to the wisely governed treatment of many affections of the upper air-tract. I am one of those who have always held —who still holds—that the clinician, the general practitioner, should usually—not to say always—control the specialist in all branches of practical medicine. I do not mean to affirm that the clinician should invariably and always treat the patient himself. I do say he should be the guiding hand—the one whose province it is to say, in most instances, to what extent it is wise and considerate for him to pursue particular lines of work.

New York State Asylum Expenditures.—Some idea of the magnitude of the requirements of the State Hospitals for the Insane can be obtained from the following statement as to staples consumed during last year: Flour, 26,235 barrels; meat, 4,749,025 pounds; sugar, 1,012,487 pounds; coffee, 321,324 pounds; tea, 75,765 pounds; butter, 941,170 pounds; eggs, 463,160 dozen. The total consumption of coal was 97,761 tons. The expenditure during the year for provisions and stores amounted to $1,027,697.13; total expenditure for clothing, $179,305.64. The commission expects that the expenditures of the current year will not materially exceed the foregoing.

SYPHILIS IN PREGNANCY.[1]

BY ROBERT A. MURRAY., M.D.,
OF NEW YORK.

THAT we do not at the present time see cases presenting the direful ravages and mutilations of syphilis which were so frequent not many years ago is due not only to a more perfect knowledge of the disease and the principles guiding its treatment, but also to the fact, to which many expert observers testify, that syphilis is less malignant and more tractable in management than formerly. This observation has, I believe, led to a false feeling of security, has diminished the apprehension exhibited by subjects of this disease, and as a result, with the removal of outward manifestations, due to the continuance of a short mercurial course, both physician and patient have ceased treatment; and the latter, on marrying, with full faith that he is cured, is rudely shocked by the direful effects to his wife and children. Later on we have those most terrible complications of nerve syphilis in the brain and spinal cord, causing ruin to health and prospects, and even death.

As obstetricians, it is our province to recognize this disease as being the most powerful factor in causing miscarriages and still-born children; and what is perhaps more distressing, children are brought into the world with, as has been well expressed by Fournier, "an inaptitude for living," to be cut down in infancy by intercurrent disease, or to die miserably from inherited syphilis. From hospital statistics these deductions become remarkably apparent; yet they are not more convincing than those obtained in private practice from a smaller number of cases. Fournier gives the following results in 167 cases of pregnancy coincident with syphilis: Cases of survival of infant, 22; cases of death of infant (abortion), premature labor, still-born, and dead shortly after birth, 145; total, 167.[2]

Dr. Le Pileur, physician of Saint Lazare, Paris, prepared statistics for ten years of the mortality among children, the issue of syphilitic mothers. He found that in 414 pregnancies 154 were terminated either by abortion or by premature expulsion of the still-born infant. Of 260 infants born at term and living, 141 died within a short time, and only 22 survived one month. This makes a total of 295 deaths in 414 pregnancies, that is to say, in round numbers, almost 3 deaths to 4 births. Among the children considered as "surviving," there assuredly were a certain number who succumbed later directly from the disease.

In private practice the physician is misled in finding a cause for abortion, premature labor, and still-born births by the ignorance of the mother as to the disease and by some fancied cause, as a fright, a nervous shock or a fall, which among the laity are generally considered the only causes of premature emptying of the uterus apart from criminal abortion. Again, the husband of the pregnant wife either thinks that the syphilis he had when a young man has nothing to do with the mishap, or when questioned, if the cause is suspected, will state that he had a chancre, which was only a small one, and with slight manifestations, which did not amount to much, and that he was assured by his physician that he was properly cured.

Up to the present time, unless a child that was still-born showed upon its skin the lesions of inherited syphilis, a diagnosis of the cause of the still-birth was rarely made, as our knowledge of the changes in the placenta, and in the new-born, was insufficient, and autopsy was very rarely allowed. For the protection of the patient in the future, and the prevention of premature labors and still-births, it is very necessary that autopsies should be obtained on the children whenever possible.

The Syphilitic Placenta.—Simpson, D'Outrepont, Virchow and particularly Fränkel have shown that the changes in the placenta, and in the endometrium of syphilitic pregnant women are the same as occur in other syphilitic lesions, that is, an increase to a large extent of the fibrous tissue, and an infiltration of granulation cells into the villi with degeneration of their epithelial covering.

According to the time of infection, Fränkel states there are differences in the placenta and endometrium. If the mother is infected during the fruitful coitus there may be endometritis placentaris, characterized by the enormous overgrowth of the decidual cells, or the overgrowth of connective tissue, as well as by syphilitic disease of the villi. If the mother is syphilitic before conception, the disease of the placenta takes the form of endometritis placentaris gummosa. If the mother is infected during the later months of pregnancy, the placenta usually remains unaffected.

Fränkel states that this infiltration of the villi with granulation cells, and their consequent increase in size and distorted shape, is characteristic of syphilis, and might serve to make certain the diagnosis of the disease. In gross appearance, syphilitic placentæ vary greatly, depending on the time of death of the child and on the period of pregnancy when it is expelled. If the child is macerated, the placenta is white, soft, and greasy to the feel; if labor is at full term, and the child is alive, the placenta is unusually large and pinkish, due to the thickened decidua, very often with attached clots showing a previous hemorrhage into the placenta, or the occurrence of thrombosis of the lacunæ; or there may be found nodes, lamellated in structure and undergoing degenerative changes in the central portion. Calcareous degeneration is also seen, but this is by no means diagnostic of syphilis.

---

[1] Read at the Twenty-second Annual Meeting of the American Gynecological Society, Washington, D. C., May 5, 1897.

[2] Fournier, "Syphilis and Marriage," p. 66.

As a result of this cell infiltration of the villi, and the proliferation of the decidual cells, there is obliteration of the blood-vessels and encroachment on the intervillous spaces, and the function of the organ is more or less destroyed, the villi themselves being destroyed by the formation of nodes. When endometritis placentaris is present, the hyperplasia of the decidual cells attaches the placenta to the endometrium, so that it may be retained firmly at points and lead to hemorrhage or septicemia. The placenta and endometrium in these cases is apt to be less bloody, and when washed the endometrium has a bacony feel, and the lochia is more watery and very much less abundant than ordinarily. No physical signs are present during pregnancy to diagnose placental syphilis.

Fetal Syphilis.—According to Ruge, eighty-three per cent. of premature and still-births have their cause in syphilis of one or both parents. We must also include the number of syphilitic children born alive who eventually die from inherited syphilis, to form a complete idea of the destructive effect of syphilis on the fetus. Syphilis is evidenced in the fetus by the early death of the latter in the uterus; by the peculiar old, wizened, and shrunken appearance of the child when born alive; by the presence of pemphigus and scaly eruptions, fissures at the mouth and anus, inflammations of the mucous and serous membranes, condylomata at the mucous orifices, and growths of the connective tissue in the arteries, constituting endarteritis. In the liver, spleen, pancreas, lungs, brain, and spinal cord circumscribed or diffuse gummatous deposits are found. These are most easily observed in the liver in the shape of minute grayish-red or grayish-white pin-head and larger-sized bodies, which under the microscope are found to be nests of well-packed embryonic cells surrounded by a dense mesh of connective tissue with radiations passing toward the normal hepatic cells in every direction. Those changes in the fetal structures are more disastrous than in the adult, because the subject is infected *ab ovo* with the special toxin of the malady.

More striking and peculiar are the changes described by Wegner, Parrot, and Hutchinson. Wegner describes a form of osteochondritis, at the epiphysodiaphyseal extremity of a long bone. In these cases premature ossification goes on with increased proliferation and growth of individual cells; or, there may be actual arrest of the bone-making process by premature sclerosis of the intercellular hyalin matrix of the cartilage. Parrot describes an atrophy, in which rosy or yellow-tinted, jelly-like foci develop at the line of junction of epiphysis and diaphysis, and in which eventually in place of bone a loose reticulum of fibrocellular structure is formed, allowing easy dislocation. In another case described by Parrot, osteophytes of varying thickness, projecting at right angles to the osseous shaft, develop from bony trabeculæ and interlace at one or several points beneath the periosteum. Under the microscope there is recognized an exceedingly irregular arrangement of the Haversian canals and osteoblasts, with filling up of the canals with granulation cells so that the arterial supply is cut off; at other points the osteophytes produce porosities strikingly similar to rickets.

The child born of syphilitic parents may not present any evidences at birth of the disease, except the peculiar old-man appearance. Subsequently, snuffles develop, then restlessness and irritability, accompanied by a peculiar moaning cry, indisposition to nurse, marasmus, and death, sometimes very suddenly and seemingly without cause, it only being explicable by the changes found in the arterial system. Again, the child may be perfectly well until a cold, digestive disturbance, or vaccination, by perturbing the system, causes syphilitic manifestations to appear.

Syphilis in the pregnant woman exhibits itself in various ways, depending on the time and mode of infection. When syphilitic before pregnancy supervenes, the ordinary signs have been, or are, present; when infected at the fruitful coitus, from a primary lesion on the man, the chancre, according to most observers, appears earlier than in the unimpregnated (at about the second week), and its course is usually more severe. The secondary symptoms are usually light, so that some have thought that pregnancy has a benign influence on the disease. In the three cases I have seen the manifestations of the disease seemed quite as severe as in an ordinary case, and when the pregnancy was interrupted by the death of the fetus and its expulsion from the uterus, the symptoms seemed in no wise ameliorated. This form of infection is certainly the most fatal to the fetus. When the pregnant woman is infected by a man suffering from the secondary effects of syphilis, the duration of the disease, its severity, the amount, efficiency, and duration of the treatment are the important factors in determining the effect on the fetus. If infected before the later months of pregnancy the disease usually kills the fetus, particularly when the disease in the father of the child is in an active stage and uncontrolled by treatment. Many authorities claim that infection in the last months of pregnancy does not affect the fetus disastrously, but to this an unanswerable argument can be made in the fact that, following Colles' law, such an infant can, and does, nurse its own mother without infecting her or showing an initial lesion on itself, while the mother will subsequently show the effect of the disease. When both parents are syphilitic, as was stated in the beginning of this article, the effect on the child is very fatal.

Time and treatment do away with the evidences of syphilis, but the amount of both time and treatment and the limit when the disease is cured, is difficult to state. I have had cases in which the time from the appearance of the initial lesion has been as long as six, and in two cases, even twelve years, yet the disease was the cause of death of the fetus. It is, however, a frequent experience to see cases in which sterility for some time will be followed by pregnancy, abortion resulting at the second or third month, subsequent pregnancies terminating at the fourth, sixth, or seventh month, and finally, after four or five pregnancies, result in the birth of a live child, with little, but still marked, evidences of syphilis. Eventually the disease, by time alone, seems to lose its force, and healthy children may be born. Later in life these children often present the enlarged glands, the red inflamed margins of the eyelids, and Hutchinson's teeth which are characteristic of inherited syphilis.

The diagnosis of syphilis in pregnancy, particularly when the father alone knows of the existence of the disease, is sometimes difficult. If the pregnant woman has been infected by a primary lesion, the secondary results will make the diagnosis certain, even if the initial sore was unobserved. When the husband denies having had the disease, however, a careful examination must be made of his person for involvement of the glands in the groin, and for the lesions of the mucous membranes. Twice I have thus shown that the husband and no other man was the guilty party. When the husband has syphilis and, believing he has been cured as there have been no active signs of the disease for some time, he impregnates his wife, the disease usually evinces itself about the middle of the third month by the appearance of mucous patches on the tonsils and pharynx of the wife. The physician who is called to a patient with sore throat, who at the same time is pregnant, will be able to determine the diagnosis from the presence of these patches, there being an absence of fever or evidence of diphtheria, and from the enlargement of the lymphatic glands, the swelling not being confined to those of the neck. Careful inspection also shows condylomata at other mucous orifices.

Consulted by patients who have had several miscarriages, the diagnosis is made positive by leading the patient's memory to the appearance of the fetus when born, or by the absence of a history of accident or other cause for abortion, and by observing the enlarged suboccipital, epitrochlear glands, etc., which are the vestiges of the disease. If the husband can be interrogated, a history of his attack of syphilis may sometimes be obtained. Some authorities state that in the absence of any other causes for frequent miscarriage, as chronic endometritis, membranous dysmenorrhea, etc., the presumption should always be acted on that syphilis is the cause, and treatment instituted accordingly. The success in the use of mercury in small doses as a tonic in building up the system might lead us to conclude without sufficient basis that the patient or her husband was syphilitic if pregnancy and a live full-term child was the result, and thus an erroneous diagnosis be made.

The Treatment of the Syphilitic Pregnant Woman.—The treatment of syphilis in the pregnant woman, when both husband and wife are cognizant of the disease, is robbed of half of its difficulties, and in the vast majority of cases, when instituted early, is successful. When, however, the patient has to be treated without feeling sick, unconscious herself of any necessity for treatment, and particularly if it is during a first pregnancy and the patient has near relatives who know of no reason for the care of a physician, and if the husband will not allow of an explanation, a problem is presented which demands all the carefulness and skill of a diplomat to solve. These considerations, in our solicitude for the welfare of our patient, often cause a physician to adopt a less effectual means of cure because it is easy and not apt to excite remark.

Mercury is the only drug that will control syphilis, either in the pregnant woman or in the non-pregnant. Many of the preparations of the drug are not easily handled, however, and some by their action on the bowels are liable to interfere with gestation. My preference is for treatment by inunction, which is disagreeable to some, and certainly is more apt to excite apprehension than when the mercury is administered by the month. I have found this method the most efficient, the most easily controlled, and least productive of such disagreeable results as salivation, diarrhea, colic, indigestion, etc. I order the mercurial ointment in bulk, and advise that a piece the size of a hazel-nut be rubbed into the skin of one upper arm morning and evening, the process being repeated the next day on the inner side of the thighs, while on the third day the inner side of the chest is utilized, and on the fourth day the arms again. If thin undergarments, such as balbriggan, are worn, and the patient takes a warm bath each night before using the inunction I have seldom seen any who complained of the treatment.

The mouth should be rinsed and the throat gargled with a weak solution of chlorate of potash and borax, to avoid stomatitis, as in all cases in which mercury is administered. As soon as the gums show redness and softness, and the blue line appears, the amount of the drug should be reduced or stopped altogether for a time. It is surprising how very infrequent the necessity occurs for the latter. Local lesions are best dressed by dusting with calomel or aristol. The baths necessarily taken by a pregnant patient treated by inunction have seemed to me to be of the utmost service in keeping the skin and emunctories active. I have never seen one of these patients suffer from uremia. When it is necessary to use mercury by the mouth, the tablets of the protiodid in one-half-grain doses three times a day, have given the best results. Mercury with chalk, in fractional doses, and the biniodid in one-sixteenth-grain doses also are highly recommended.

Syphilis always produces a decrease of the red globules in the blood, an increase of the white, and a profound deterioration of the system, which, added to the condition of hydremia and anemia, with retention of waste matter due to the pregnant condition, reduces the patient's vitality extremely. These conditions should constantly be borne in mind, and the judicious use of good food, fresh air, exercise, the ferruginous tonics, arsenic, strychnin, and cod-liver oil should be advised; indeed, specific treatment, while the most powerful tonic, is frequently inefficient if these adjuvants to overcome anemia are omitted.

The effect of the mercurial administered according to modern methods is tonic and constructive in the highest degree, as has been shown by Keyes and Taylor, and by many other syphilographers. The improvement in the system by a course of mercury is constantly shown by an increase in the number of red blood globules and a healing of lesions. These facts should be borne in mind in the treatment of the pregnant syphilitic. The iodids in my hands have not been of service in the treatment of these cases, and the fear of the effect on the uterus has prevented their use.

After labor the mother still must be treated, and frequently the child as well. Fortunately the treatment of both can be carried out by giving the mercurial to the mother, for it passes to the child in the milk. As the infant grows older, the mercurial ointment may be rubbed on its flannel band, as enough of the drug will be absorbed by the skin. The mother and child should be treated also in order to protect others who come in contact with them, and kissing and fondling of the babe by relatives should be prevented.

At the time of confinement great care should be exercised by the accoucheur and nurse to prevent infection. Syphilitic patients seem peculiarly liable to septicemia, so more than ordinary aseptic precautions should be taken. As frequently the mother is too weak to nurse her child properly, and as its depreciated condition demands the best of nutrition, a wet-nurse should not be employed on account of the danger of her becoming infected, but sterilized food should be regularly given, and this should frequently be aided by inunctions of cod-liver oil, which in my hands has often saved these poor infants.

When miscarriages have occurred from the presence of syphilis, and again, even when a child has been carried once to full term, we are not sure that subsequent pregnancies will terminate in the latter happy way, unless we treat the patient specifically not only for the disease but also for its effects.

As was stated in a former part of this paper, an endometritis is often present as a result of a miscarriage, and in many cases I have considered it the cause of subsequent abortions. The uterus is enlarged and subinvoluted, there is a purulent and watery, sometimes fetid, leucorrheal discharge, and the uterine mucosa feels, when available to the touch, hard, bacony, and nodulated. I have found that if the uterus be thoroughly curetted and painted with iodized phenol, or lightly tamponed with iodoform gauze so as to allow of drainage, the uterus becomes lighter, the discharge clears up, and with the specific treatment continued, the patient is more quickly cured, the disease being rendered innocuous in future pregnancies. In one instance in my experience, in which eight abortions and premature births had taken place, at short intervals, thorough curetting and treatment made possible the delivery of a full-term living child at the next pregnancy.

All other manifestations of the disease should be treated according to the well-known principles, which need not be enumerated here, the vital point being that the treatment should be vigorous and persistent in both the wife and husband, mercurials, iodids, and tonics being administered until the disease is controlled. After a labor in which the child is dead, both husband and wife should be told of the danger of a fatal result to the fetus should pregnancy result without prolonged and thorough treatment, and the risk of pregnancy should be avoided until a reasonable time has elapsed in treatment.

WHAT SYMPTOMS SHOULD WE CONSIDER MOST IMPORTANT IN DECIDING AS TO THE ADVISABILITY OF OPERATION IN MASTOID DISEASE?[1]

By GORHAM BACON, M.D.,
OF NEW YORK;
SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; CONSULTING SURGEON TO THE ORTHOPEDIC HOSPITAL.

THERE are two forms of mastoid disease to which I desire to refer in this paper—first, an inflammation of the mastoid cells secondary to an acute otitis media; and second, an inflammation of the mastoid cells occurring in connection with a chronic purulent otitis media.

Since the influenza made its appearance in this country, some seven years ago, there have been, according to my experience, many more cases of mastoid disease observed than ever before. It is only a few years ago that but twelve, or at most twenty, cases of mastoid disease were recorded in the annual report of the New York Eye and Ear Infirmary. In the report for 1896 there were 135 mastoid operations recorded. Formerly, it was the exception for the mastoid cells to be simultaneously involved in a case of acute otitis media. During the past few years this condition of affairs has been very frequent. A patient will have a sudden severe earache, which is followed in a few hours by a bulging of the drumhead and symptoms of mastoid inflammation. Of twenty cases that within a short period of time have come under my observation in private practice, thirteen were in children, whose ages varied from a few months to thirteen years. The age of the remaining seven patients ranged between seventeen and fifty-five. Of the latter, there were three males and four females. Of the children, eight were males and five females. In sixteen cases, the inflammation of the ear was due to cold, influenza, or tonsillitis; in one it followed bronchitis, one was due to whooping cough, and one to measles. In one the inflammation was undoubtedly caused by the cutting of four molar teeth. In two cases, due to cold, the earache was undoubtedly aggravated by teething. Of these twenty patients, all developed acute otitis media. In seventeen there was acute inflammation of the mastoid cells, and in seven it was necessary to open the mastoid process. In ten, recovery took place without operation. Of the last named, the drumhead was punctured in six cases.

In one of these twenty cases, *viz.*, that of an infant, several months old, in whom alarming symptoms developed suddenly, suggesting a meningeal complication, puncture of the drumhead gave speedy and marked relief. In another, twenty-two months old, who had had a capillary bronchitis, there suddenly developed an acute otitis media on each side. The temperature rose to 105° F. I punctured both drumheads and the temperature fell to 102° F. In this case it was necessary to incise the drumheads several times. Each time that the perforation closed, the temperature would suddenly rise to 105° F. The child made an excellent recovery. In a child eight years of age, who had a sudden attack of earache, the temperature was 102° F. An examination of the ear showed a severe inflammation of the bony auditory canal with redness and bulging of the right membrana tympani. An ice-bag was applied after the artificial leech had been used, as there was extreme tenderness over the mastoid process. On the following day inflammation occurred in the left drumhead with involvement of the mastoid process. The same treatment was followed out here. There was a copious discharge from the ears, but on the third day it was necessary to make a free incision again in each drumhead, as the discharge was scanty. The temperature gradually declined and on the ninth day became normal. In a child of eleven, who had a sudden attack of *grippe* and tonsillitis, followed by earache on the lelt side and inflammation of the mastoid process, the temperature was 103° F. There was tenderness on pressure over the middle and lower thirds of the mastoid and bulging about Shrapnell's membrane. In spite of the treatment, which consisted in the application of leeches, paracentesis of the drumhead and the use of the ice-bag, the mastoid symptoms became more marked and the temperature rose to 106.2° F. It was necessary to open the mastoid cells and to remove granulations and softened bone. The temperature on the day after the operation varied from 104.2° to 105.2° F. At this time evidences of pneumonia were discovered. Two days later, the temperature began to decline gradually and perfect recovery followed. I had another case under observation very similar to the preceding, in which the first symptom was a severe earache. Paracentesis was performed. The temperature remained high and symptoms of pneumonia were marked. The child recovered. In cases of acute otitis media following influenza, and in which the temperature remains high after the membrana tympani has been incised or the mastoid cells opened, we should bear in mind the possibility of the existence of a latent pneumonia, as well as other complications.

---

[1] Read at the Thirtieth Annual Meeting of the American Otological Society, held at Washington, D. C., May 4, 1897.

In the case of acute otitis media occurring in connection with measles, the temperature suddenly arose to 104° F. There was inflammation and bulging of both drumheads, together with tenderness on pressure over the antrum and lower third of the mastoid process on each side. Puncture of each drumhead and the application of the Leiter coil, with frequent syringing of the auditory canals, was the treatment employed. After the paracentesis the temperature fell to 100° F. Of the adults referred to, one was a gentleman, fifty-five years of age, who had an attack of influenza, followed by an earache on the left side. When I first saw him there was extreme tenderness over the lower third of the mastoid, and a small perforation of the drumhead, with a thin, scanty discharge. I immediately enlarged the opening in the membrane and ordered small doses of calomel and the application of the ice coil. The temperature varied from 99.5° to 100° F. On the fifth day after my first visit, the temperature became normal. The patient made an excellent recovery. A case where it was necessary to open the mastoid cells was that of a young woman, seventeen years of age, who had a severe attack of influenza and an earache.

There was a scanty discharge at first, but it gradually became more copious. The drumhead was perforated in the lower anterior quadrant. The ice-coil was applied on account of mastoid tenderness. The drumhead gradually healed and the patient seemed to be on the road to recovery, when suddenly she again had severe pain in the mastoid. In this case the temperature was slightly above normal, never rising during the course of her illness above 102° F. It was necessary to remove softened bone and granulations from the antrum down to the tip. The patient recovered.

I have never seen a case of acute inflammation of the mastoid cells without some elevation of temperature, and I look upon this symptom as having a very important bearing upon the diagnosis. The temperature may vary from 99.5 F. to 100° F., in one case, while in another it may be much higher. As a rule, in simple cases, the temperature is apt to be much lower in adults than in children. In children, the temperature frequently is 104° or 105° F. A patient with a temperature slightly above normal may have extensive caries in the mastoid, and we may find at operation that there is an opening into the middle cranial fossa, or that the lateral sinus is exposed. This condition of affairs I have frequently observed, so that a high temperature does not necessarily indicate a very severe inflammation of the mastoid cells. If a patient is under observation who has had an acute inflammation of the middle ear for a week or ten days, and if in spite of treatment there remains tenderness on pressure over the mastoid process, with a slight elevation of temperature, I consider these symptoms, when taken together, as very characteristic of mastoid disease. Pressure should always be made on both mastoids, however, as occasionally such pressure causes pain in a healthy mastoid process.

It was formerly taught that edema and redness behind the ear were evidences of mastoid disease. Operation should not be deferred until these symptoms appear, as valuable time may be lost by so doing. The fact must not be overlooked that redness and edema over the mastoid, and tenderness on pressure, may occur in cases of furunculosis of the external meatus, so that these symptoms do not always indicate mastoid inflammation. Bulging of Shrapnell's membrane, with drooping of the posterior and upper cutaneous lining of the external meatus, are, to my mind, absolute symptoms of mastoid involvement, and I believe that in such cases it is always necessary to perforate the mastoid cells.

As to inflammation of the mastoid occurring in connection with chronic purulent otitis media, a patient recently came to my clinic who had had a discharge from the ear for ten months. He had pain and tenderness over the mastoid, especially the tip. A leech was applied. He returned in a few days and there was evidences of slight facial paralysis on the same side as the ear inflammation. He was admitted to the hospital, and, under ether, I found great destruction of bone, with the mastoid cells filled with pus and broken-down tissue. The lateral sinus was exposed, and there was a large carious opening in the tympanic roof. This was enlarged and considerable pus escaped from the middle fossa. The boy recovered. In cases of chronic purulent otitis media, I think there is no question but that operation should be at once resorted to when mastoid symptoms develop.

As to treatment of acute otitis media, the artificial leech should be applied at once. If there is any bulging of the membrana tampani, it should be freely incised, and in cases of otitis media, due to influenza, especially when there is much pain and fever, an early puncture should be made. When the mastoid cells are involved, the local abstraction of blood is most important, and this should be followed by the application of the Leiter coil. The latter is much superior to any ice-bag, and should always be used when possible. A free incision should then be made in the drumhead along its posterior border from just behind the stapes down to the lowest point of the membrana. I always use a large knife for this purpose; never a paracentesis needle. I generally leave the ice-coil in place for forty-eight hours at a time and then remove it, as the cold generally relieves the pain but sometimes masks the other symptoms. The cold can be reapplied, but should not be constantly used after the first two days. I give calomel in small doses at the commencement of the disease until slight catharsis is produced. Tincture of aconite is also a valuable remedy in the inflammatory stage. Frequent douching of the ear with a boracic acid, or occasionally a mild bichlorid solution, is necessary as long as the secretion is profuse and the acute symptoms present. I almost always administer chloroform when incising the drumhead. Especially should this be done in the case of children. This anesthetic should be used most cautiously, however, and only in such quantity that the patient will feel no pain when the incision is made. I sometimes employ Politzer inflation to remove the secretion and occasionally apply suction by means of Siegle's otoscope for the same purpose, but great caution should be exercised in the application of either method. If the mastoid symptoms persist in spite of treatment, one should not hesitate to open the mastoid cells at once.

CLINICAL MEMORANDA.

EXTRA-UTERINE PREGNANCY OCCURRING TWICE IN THE SAME FALLOPIAN TUBE.

By T. F. PREWITT, M.D.,
OF ST. LOUIS;
PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY AND OF CLINICAL SURGERY IN THE MISSOURI MEDICAL COLLEGE;
SURGEON TO ST. JOHN'S HOSPITAL, ETC.

IN view of our preconceived ideas of the etiology, evolution and terminations of ectopic gestation, the occurrence of this condition twice in the same tube would scarcely seem possible. If we admit its occurrence in the case I report, it is certainly unique, as I am not aware of any similar case on record.

In a paper read by me before the State Medical Association of Missouri, at Sedalia, on the 19th of May last, on the subjecf of extra-uterine pregnancy, I reported, among others, the case of Mrs. T. D., then twenty-six years of age, the mother of three children, who, after passing her regular monthly period for four or five days, commenced to flow, which she regarded simply as delayed menstruation. This flow continued for four or five days, when on November 15, 1895, it suddenly stopped. She supposed she had taken cold, especially as she had some pain. On November 18th she was taken with severe pain in the left side of the pelvis, which "doubled her up," as she expressed it, and which was accompanied with faintness and diarrhea.

I made a diagnosis of tubal pregnancy, with rupture of the sac, and advised celiotomy, which she emphatically declined. In the meantime there was a return of the bloody flow. Her temperature rose to 103° F., and her pulse to 130 per minute, with great abdominal tenderness. The flow continued for about three weeks. There was a gradual subsidence of the more acute symptoms, but a distinct tumor or swelling, with great tenderness, remained for months. About December 13, 1896, she consulted me and stated that she should have been unwell about the 10th but had had only a slight show, and as she had been perfectly regular up to that time, she was apprehensive that she might be pregnant, a condition to which she was very averse. I suggested it might be the effect of cold only, and that the next period might come around all right, and advised her in any event to leave the matter alone. On January 21, 1897, I was called to see her, and found her suffering great pain. She gave me the following history:

On the 14th of the month a profuse bloody flow had made its appearance, coming on with a gush like that from a hydrant. On the first or second day of the flow, a membranous, fleshy something came away, but she did not preserve it. The bloody discharge had continued quite free, without marked pain, up to the 21st, when in the afternoon she was seized with violent pain in the left pelvic region, which was accompanied by faintness and vomiting. When I saw her the pain was still very severe and the tenderness in the suprapubic region great. Upon digital examination, a distinct tumor in the left pelvic region could be felt. It was clearly not connected with the uterus, there being a distinct interval between. It was excessively painful to the touch, and seemed about as large as a small fist and somewhat elongated. I thought I could detect indistinct fluctuation. She had no fever, but a quickened and rather depressed pulse.

I was somewhat puzzled to account for the condition. Under the circumstances I should unhesitatingly have made a diagnosis of tubal pregnancy with rupture of the sac. With a previous history and a group of symptoms which clearly indicated an extra-uterine pregnancy in the same tube, with a rupture of the sac, I hesitated. I explained to her that some serious accident had happened in the pelvis and that it indicated extra-uterine pregnancy, and that a celiotomy ought to be performed at once. To this she again objected. I gave her a hypodermic injection of one-third of a grain of morphin to relieve her great suffering, and left her, with instructions to send for me at once if any urgent symptoms arose.

The next morning, January 22d, in response to an early telephone message, I saw her again and found that she had rested fairly well during the night, but that some pain had again set in in the morning. She was quite pale, with a pulse 120 beats to the minute and depressed, but there was no rise of temperature. Digital examination produced the same excruciating pain and revealed the same swelling at the left of uterus. I explained to her that the rupture of the sac of an extra-uterine pregnancy had occurred, that the condition was an exceedingly critical one, that if she survived the immediate dangers she must expect to go through the same ordeal of suffering and ill-health as before, and advised her to submit to an operation. After much hesitation she consented, but not until late in the afternoon.

Aided by my assistants, Drs. Geitz, Schlueter, and Rohlfing, I proceeded to open the abdomen, making an incision of about two inches through the peritoneum. Passing in two fingers I found blood welling up from the pelvis, and readily recognized extensive adhesions. The uterus was retroverted and held by bands; the left Fallopian tube and ovary were somewhat prolapsed and firmly bound down. A rounded tumor could be felt about two inches to the left of the uterus in the track of the tube, which, upon attempting to raise it, became loose and dropped into the pelvis. It proved to be a firm mass made up mostly of clotted blood larger than a walnut. With my fingers I endeavored to detach the adhesions from the tube and ovary, but only succeeded in part. In fact, I was compelled to make a pedicle of a mass of adhesions that bound the ovary down too firmly to be detached. The tube and ovary were then removed, the pelvis sponged out with sterilized gauze and the abdomen stitched up with silkworm gut, without flushing or drainage. A large rent was found midway in the Fallopian tube, from which the clot had escaped during the early manipulation. The fimbriated extremity was hermetically closed, the tube appearing as though two sacs existed, the one from which the above-mentioned clot had escaped, and a larger one at the outer end, with something of a constriction between. No fetus was found, but a careful search was not made to find it in the fluid of the belly.

That a similar accident had occurred more than a twelvemonth before, involving the same Fallopian tube, the history of the case, the identical group of symptoms in each case, and the pathologic conditions found at operation clearly demonstrated. If it be admitted that the accident in November, 1895, was a tubal pregnancy with rupture of the sac, how could a second pregnancy occur in the same tube? That it did occur, I think is certain. It might be contended that the failure to find the fetus at the time of operation leaves a doubt as to the diagnosis of ruptured tubal pregnancy. Upon this point, Mr. Tait says: "I have never seen an intraperitoneal hematocele that was not due to ruptured tubal pregnancy"; and when we find a tube dilated into a sac until the distension has caused its rupture, followed by an extravasation of blood in quantity, what other conceivable explanation can be given when we know that in many similar cases the fetus has been found? The criticism might have more weight if applied to the first accident, since actual rupture of the tube was not verified and it *might* have been an extraperitoneal hematocele (intraligamentous), though such a condition is scarcely possible in view of the evidence of peritonitis which was found to have followed.

In what condition was the tube left after its rupture, after the peritonitis set up in connection with it, and after the absorption of the blood poured out at the time of the accident and the cicatrization and repair of the rent in its walls? It must be conceded that in accordance with the scheme of tubal pregnancy as at present understood, the tube should be patulous from the uterus to the *morsus diaboli* to permit of the passage of the ovum, on the one hand, and the spermatozoa on the other.

According to Bland Sutton, while the tube is expanding from the enlargement of the ovum within it, and the mucous membrane is stretched and its glandular folds effaced, "curious alterations are taking place at the abdominal ostium, which in most cases gradually bring about its occlusion, an event usually completed by the eighth week. During the first four weeks the congestion of the parts causes turgescence of the fimbriæ as well as of the muscular and serous tissues adjacent to them. When the parts are thus swollen the margin of peritoneum adjacent to the ostium is very conspicuous, and forms an irregular ring over the fimbriæ. In another fourteen days this ring projects beyond the fimbriæ, and lastly contracts and hermetically closes the ostium."

Admitting the correctness of my diagnosis in this case in the first instance, we must suppose that one of two things occurred, first, either the rupture in the first case occurred before the closure of the abdominal ostium, leaving the lumen of the tube after the repair of the rent still patulous, or, second, the fimbriated extremity having been closed, an ovum must have passed down the right tube, become impregnated in the uterus, and been forced up by muscular action into the left tube in the manner suggested by Tyler Smith and Kussmaul (referred to by Playfair).

The following is the report of the microscopic examination of the clot by Dr. Carl Fisch of this city: "The clot was carefully examined in every direction, but it was not possible to demonstrate the presence of an ovum or of its remnants. There were, however, several places where chorionic villi were present in great numbers, some torn off and single, while others formed small groups connected by parts of the membrane. A number of these villi showed evident signs of mascerataion and disintegration; others were quite intact and normal in appearance. In the latter, vascular structures could be plainly made out, showing that the embryo must have been older than two weeks."

NOTE.—Since this paper was written, my attention has been called to a most interesting paper by Dr. H. C. Coe of New York in *The American Journal of Obstetrics and Diseases of Women and Children* for June, 1893. In this article he reports one case of his own of undoubted successive tubal pregnancy in which an old unruptured tubal sac containing fetal bones was situated near the uterus and another of recent development near the fimbriated extremity which was patulous. The more recent sac had ruptured and contained a living fetus of four months. He also cites Hayden's case, also a double tubal pregnancy in which an old sac containing fetal bones was found lying apparently just outside the free extremity, while a second sac developed near the fimbriated extremity had ruptured.

TWO CASES OF FIBROID TUMOR OF THE UTERUS.[1]

BY AUGUST SCHACHNER, M.D.,
OF LOUISVILLE, KY.;
DEMONSTRATOR OF ANATOMY IN THE LOUISVILLE MEDICAL COLLEGE; VISITING SURGEON TO THE LOUISVILLE CITY HOSPITAL.

THE following two cases of fibroid tumor of the uterus are of more than usual interest, especially the first one, on account of the enormous size and peculiar multinodular conformations of the growth.

CASE I.—D. W., aged fifty-four years, married, nulliparous, consulted me about a large abdominal tumor, which upon examination proved to be a uterine fibroid. The tumor reached almost to the costal cartilages, and from external appearances the abdomen resembled in size that of a woman at full term. Upon external palpation and manipulation the growth was found to be slightly movable, the motion being limited owing to its enormous size. Contrary to the rule, menorrhagia was not of any consequence as a symptom in this case. There were, however, some symptoms referable to the bladder, such as inability to retain urine for any length of time, etc. By vaginal examination the cervix and a portion of the body of the uterus appeared to be normal, but surrounding the entire fundus of the organ could be felt a fibroid mass.

The woman was prepared for operation by the administration of tonics, salines, heart stimulants, etc., the preparation extending over a period of a week. The incision reached almost to the ensiform cartilage. The tumor appeared to be in halves, the upper half being the larger. The surface was very nodular. It was easily delivered, there being some slight omental adhesions, which were quickly tied off and separated. The pelvis was elevated at the time the delivery was accomplished. From experience gained in another case I have found it best to keep the woman in a horizontal position until the tumor is delivered, since the Trendelenburg posture may become a source of danger where large tumors exist, owing to their tendency to fall toward the diaphragm. When large growths are suddenly delivered from the abdominal cavity they very often produce profound shock, owing to the rapid dilatation of the omental vessels which before were compressed by the tumor, but by sudden relaxation drain, so to speak, the larger part of the volume of blood into the vessels in the abdominal cavity, thereby causing syncope, which might produce death. An assistant had been assigned the duty of elevating the table to an angle of 45° as soon as the tumor had been brought out through the abdominal wound. A rubber ligature was now temporarily thrown around the growth, including both tubes and ovaries, and the mass was cut away. The pedicle was surrounded by a serre-neude and the stump treated extraperitoneally. The woman was taken from the operating-table with a pulse of 70, and throughout her convalescence the pulse never reached 100, although the temperature on several occasions registered between 100° and 101.5° F. There was no nausea, and the post-operative course was as uneventful as could be desired. The pedicle came away on the seventeenth day and the remaining cavity healed by granulation. The total weight of the tumor was twelve pounds, although it was judged by some as weighing at least twenty-five pounds. Its dimensions were as follows: Longest measurement, sixteen inches; widest measurement, ten inches; and thickest, seven inches.

CASE II.—Francis R., aged thirty-seven, married, nulliparous, was examined by me three years ago, and at that time a small uterine fibroid was discovered. She was again examined recently, when it was found that the tumor had enlarged to the size of a cocoanut, while at the same time a mass could be detected on each side of the tumor in the broad ligaments. Owing to the rapid growth of the tumor, and some vesical and rectal disturbance of which she complained, an operation was advised and agreed to. The woman was in very good health and required but little preparatory treatment.

The abdomen was opened, and it was found that, in addition to the fibroid, there were cysts of each ovary. On the right side the cyst was about the size of the adult fist, on the left about that of a goose egg. There were no adhesions, but the entire growth was deep in the pelvis, and was delivered with considerable difficulty. I had intended to do a complete hysterectomy, but owing to the time consumed in delivering the tumor and cysts, it was thought best to use the serre-neude, which, however, did not control the hemorrhage, and in tightening the wire the instrument slipped clear of the pedicle, so that finally total extirpation became necessary. Complete hysterectomy was performed, and the field of operation closed in by flaps dissected from the anterior and posterior surface of the tumor. The entire pelvis was closed, save the two stumps of the ovarian arteries on each side. These were left exposed and protruding into the general peritoneal cavity.

The operation consumed an hour and three-quarters, and, notwithstanding the time and the loss of blood, the patient left the table with a pulse of 108, and, considering the attending circumstances, was of very fair volume. The temperature did not exceed 100.5° F., and the pulse did not reach 100 after reaction was established. The stitches were removed on the eighth day, primary union having taken place throughout. The post-operative course was absolutely devoid of complication. The tumor in this case weighed about five pounds.

MEDICAL PROGRESS.

Appendicitis at One Year.—TAYLOR reports in the *Boston Medical and Surgical Journal* of May 27, 1897, a case of appendicitis occurring in a child one year old. The attack began with vomiting and pain, but the diagnosis was not made at first, and operation was not performed until the fourth day. An incision was made in the median line on the supposition that there was an intestinal obstruction. The abdomen contained a large amount of thin pus, and through a second incision the appendix was removed and the abdomen flushed with boiled water. Death occurred in eight hours.

---

[1] Read before the Louisville Clinical Society.

Cases of Peritonitis in Children Caused by the Pneumococcus.—In *La Presse Medicale* of February 27, 1897, is an article on the above subject by BRUN. It is of assistance in helping to clear up the complicated and still obscure subject of peritonitis. Brun describes three cases occurring in children, which, with two previously described by himself, and others described by Sevestre, Galliard, Moizard, and Kirmission (fourteen in all), make up a clinical and anatomic picture sufficiently characteristic to render a diagnosis fairly easy. Of these fourteen cases in which the diagnosis has been confirmed by bacteriologic examination, eleven occurred in girls. In all of the cases the peritonitis was encysted and situated below the umbilicus. It began, as all cases of acute peritonitis begin, by severe abdominal pain, fever, vomiting, and with diarrhea. This storm soon passed over, and as the fever assumed the type seen in suppuration, there was observed above the pubis and in the iliac fossæ tumefaction with dulness, sometimes with fluctuation. This localization is almost pathognomonic, especially when accompanied, as it was in at least nine of the fourteen cases by a smoothing out (*deplissement*) or by fistulization of the umbilicus. In a case recently seen, by not heeding this smoothing out of the umbilicus, Brun mistook a case of pneumococcic peritonitis for appendicitis.

The prognosis after operation is good. Of these fourteen cases, eleven patients recovered, ten after laparotomy, and one without operation with discharge of pus through the umbilicus and vagina. In several cases the operation was no more than the opening of an abscess.

With reference to the etiology of this disease little is known. The diplococcus lanceolatus is often found in the uteri of young children, and the fact that so many of these cases have occurred in girls excites a suspicion that the cocci have found their way through the tubes or walls of the uterus into the peritoneal cavity, but as yet this is nothing more than supposition.

THERAPEUTIC NOTES.

For Hemorrhagic Metritis.—

℞ Fl. extract of ergot . . . . ℥ i
Fl. extract of hamamelis } aa . ℥ ss.
Tr. cinnamon }
M. Sig. A teaspoonful every two hours.—*Chase.*

Mixture for the Treatment of Streptococcic Sore Throat in Children.—

℞ Tincture of strophanthus } aa . m. x
Anisated spirit of ammonia }
Distilled water . . . . . ℥ iiss.

M. Sig. A teaspoonful every two or three hours (for children from ten to twelve years of age).—*Professor von Widerhofer.*

Vertigo in Arteriosclerosis.—GOARCON (*Rev. de Therapeut.*, April 15, 1897) recommends the following prescription for the vertigo which so often accompanies sclerotic arteries:

℞ Iodid of soda . . . . . ʒ ii
Distilled water . . . . . ℥ viii.

The dose is one or two teaspoonfuls three times a day. The unpleasant taste may be masked by syrup of bitter-orange peel, or by milk. Hygienic treatment should accompany the medical treatment. The patient should avoid mental or physical over-exertion, should live as much as possible out of doors, should eschew a too-exclusively meat diet, piquant sauces, fish, pastry, etc. Alcoholic liquors and tobacco should be absolutely forbidden.

Epithelioma of the Face Cured by Injections of Methyl Blue.—DUBARRY (*Rev. de Therapeut.*, April 15, 1897) reports a case of epithelioma of the chin cured by interstitial injections of a ten-per-cent. aqueous solution of methyl blue. At first an injection of twenty-five minims was made every two days. Later the amount was decreased, and only one or two injections were made during a week. The entire period of treatment was six months. The tumor atrophied, and at the end of the period of treatment only a fibrous cicatrix remained. Eight months later there had been no recurrence.

Mineral Waters in the Treatment of Pulmonary Emphysema.—CAZAUX (*Rev. de Therapeut.*, May 1, 1897) speaks of the advantage to be obtained in certain cases of emphysema by the use of mineral water. Naturally, relief would be expected only in those cases in which the dilatations include a few acini with the preservation of a considerable portion of the elastic fiber. In emphysema of this character, especially if it is of a bronchitic origin, relief, and in many cases absolute cure, may be confidently expected. Such cure is produced in two ways: (1) by a modification of the bronchial mucous membrane, putting it in a condition to resist external changes of temperature; (2) by restoring the conductility of the elastic fibers upon which normal expiration depends. In arthritic subjects mixed bicarbonate waters are indicated, while patients of arthritic temperaments suffering from catarrhal asthma should take waters containing sulphur or soda, either alone or combined with metallic sulphids.

Novel Method of Irrigation in Empyema.—ZEMAN (*Rev. de Therapeut.*, May 1, 1897) has treated a number of cases of empyema with fistula by warm baths. If the fistulous opening is below the level of the fluid, it is evident that if the patient inspires and expires freely there will be a current of water into and out of the pleural cavity much stronger than can be obtained by simple irrigation. Clumps of coagulated blood and fibrinated masses are by this means washed out which could not have been obtained by simple lavage. The baths were given in boiled water cooled to the temperature of the body, and lasted ten or fifteen minutes. The general condition of the patients was much improved, and no accident was observed to follow this treatment.

SATURDAY, JUNE 19, 1897.

THE NEW YORK UNIVERSITY BELLEVUE HOSPITAL MEDICAL SCHOOL.

THE announcement made in last week's MEDICAL NEWS that the consolidation recently entered into by the University Medical School and the Bellevue Medical School for the purpose of organizing a medical department of the New York University had been annulled, is authoritatively confirmed.

The announcement of the consolidation was welcomed by all who are interested in the progress of medical education. The possibilities that presented themselves in the organization outlined by its promulgators tempted the imagination to grand flights in anticipation of what the future held in store, in the realization of a magnificent medical institution that would surpass anything yet contemplated. All these dreams have been dissipated, and affairs seem to have been restored to the *statu quo* previous to the attempted consolidation. The responsibility for the final steps that led to the separation is not difficult to place, but the original basis of the misunderstanding is doubtless to be found in the failure on the part of both parties to thoroughly comprehend the difficulties inherent in the consolidation of two old-time friendly but vigorous rivals. The proceedings had not reached a stage of advancement that would prevent Bellevue withdrawing with honor from the contemplated agreement; and this is what has occurred, the step having been taken at the formal solicitation of the representatives of the University Medical School.

With this brief interregnum in her existence, Bellevue is, therefore, again free to take up her career at the point at which the interruption came and go forward with the enlarged plans contemplated after the disaster by fire which befell her building in March last. The *entente cordiale* existing between the two institutions seems to have been strengthened rather than disturbed by the intimate contact necessitated by the consideration of the serious questions involved.

TWO CONGRESSES.

ONE month ago there were in session, under the shadow of the National Capitol, two bodies with singularly similar titles. Both were "Congresses," one the Congress of Physicians, the other the Congress of statesmen or politicians, both popular bodies, both concerned with the advancement of the good of the public in general—and of themselves in particular, incidentally. In both the members were supposed to be picked men, chosen on account of their skill and experience, in matters pertaining to their special spheres.

But here the resemblance abruptly terminates, and it is not to the discredit of the medical body that it does so. To the casual observer who watched them both at work, the contrast was most striking. One met three times a day, and every session was crowded with productive work; the other met twice a week to devise ingenious and entertaining methods of killing time and solving the great classic problem of "how not to do it." In the one the proceedings were dignified and impressive; the speeches, from the broad and thoughtful address of the President to the superb discussion upon the metabolism of the ductless glands, were of marked ability and vigor, every statement that of an expert, and the whole atmosphere that of courteous, but keenly critical, attention and interest. In the other was a Babel of confusion and boredom, of hand-clapping, paper-rustlings, audible expectorations, hands in pockets, feet on desks, eyes on ceiling, while every speech displayed an ignorance of the simplest facts and most primary principles of finance, of economics, of taxation, and of international law. The proceedings of the one were eagerly perused and the decisions respected and recognized as high authority by the entire profession which it represented; every movement of the other was regarded with suspicion bordering upon contempt, and a sigh of relief will be breathed by the vast mass of its constituents when it finally adjourns.

The differences between the two bodies are real and striking, and we have a right to inquire the reasons for them.

In the Congress of Physicians and Surgeons we have a body of some six hundred men, selected from every part of the Union, including in its ranks a considerable portion of the great leaders of professional thought, and representing a constituency of about 75,000 medical men, and yet not one of them is a member of the National Congress, even by chance. More than this, scarcely a single one of the constituency whom they represent is to be found in the political body, and we doubt very much whether the majority of those gathered together in Washington have a particle of influence, and in many cases even an acquaintance, with those who are supposed to represent them in the sister body.

The late Congress of the American Association for the Advancement of Science, and the Association of Charities and Corrections as well, disposed of its executive and personal business in a couple of half-hour executive sessions, and reserved eight-tenths of its time for the genuine purpose for which it assembled, while in either house of Congress days and weeks are wasted in sparrings for personal advantage, private bills, special pensions, and schemes of personal plunder generally. This is due largely to the caliber and character of the men of which the different bodies are composed.

In our own particular realm, we have just had a most unpleasant experience with the medical incompetency of the National Congress, in its unwillingness to consider and utter inability to appreciate the importance of the appointment of a National Department of Public Health. Nor is it simply its refusal to agree with the almost unanimous wish of the profession in regard to this matter that is most striking, for that might be based upon good and sufficient reasons of economy or policy, but it is its hopeless ignorance of, and barbarous indifference to, the really vital principles involved. There has never been even a shadow of an attempt to discuss the question upon its merits. The impression seems simply to prevail that the scheme has "nothing in it," and hence it does not interest Congress.

As to the scientific incompetency of the National Legislature, we have a still more striking instance, in the question of the bigoted, reactionary laws upon the subject of animal experimentation which is now pending and against which there seems not a single member with either the knowledge or the courage to raise his voice.

The great realm of sanitation, of preventive medicine, is opening up more and more widely every day, and "our duty to our patients," in this, the nineteenth century, absolutely demands that we should go into the halls of the legislature, into the municipal council-room, into the State and National cabinets, just as much as into the hospital, and into the sick room. Not from any petty desire on the part of the profession to be "represented" or get its share of "recognition," but for the best interests of the whole community, and of those who are committed to our care. The only things which keep us from it are: first, that degrading old tradition in the community that a doctor has practically no political rights. The other obstacle is our own indolence and indifference, or worse, a selfish absorption in our own interests and cowardly fear of making enemies or losing reputation. But our end is not to be attained by a mere willingness to accept a nomination to Congress, or by urging ourselves for cabinet positions, but by hard, prosaic, unremunerative, often thankless work by each one of us in his own precinct, his own ward, his own county. An intelligent and disinterested element in any community is bound to win if it will only set itself to work. And if we, in combination with the truly patriotic and thoughtful men of other fields and professions, could succeed in returning to Washington a body as able, as upright, as dignified, and as truly representative as the body which has recently closed its sessions in the halls of the Columbian University, we should have done more for the general progress of the race than by any other one movement in which we could have taken part. And, from a purely professional standpoint alone, the gain in comfort, health, and longevity to our patients would be greater than from even the discoveries of a Koch, a Metschnikoff, or a Lister, and just as genuinely legitimate an aim of true medical ambition.

OBITUARY.

DR. WILLIAM T. LUSK OF NEW YORK.

We regret to announce the sudden death from apoplexy of Dr. William T. Lusk at his home in New York on Saturday, June 12th. The news came with painful surprise to all his friends. He had been in his usual health up to the time of the attack and was engaged in packing his satchel preparatory to spending Sunday with his family in the country when the summons came.

Dr. William Thompson Lusk was born in Norwich, Conn., May 23, 1838. He entered Yale College in 1859, but during his sophomore year he left to enlist in the army. Entering a New York regiment as a private, he displayed so much force of character that in three years he rose to be assistant-adjutant general. He then retired from the army, came to New York, entered upon the study of medicine, and was graduated from Bellevue Hospital Medical College in 1864. He immediately went abroad and spent four years in study at Edinburgh, Paris, Vienna, Prague, Heidelberg, and Berlin. He was professor of physiology in the Long Island Hospital Medical College from 1868 to 1871, and lecturer on the same subject at Harvard Medical School in 1870–71. During these few years he gained the reputation of being a brilliant physiologist and a most interesting lecturer. In 1871 he was elected to the Professorship of Obstetrics and Gynecology at Bellevue Hospital Medical College, which position he retained to the time of his death.

In entering upon this new field of labor, Dr. Lusk threw all the energy of his enthusiastic nature into the study of obstetrics as his chosen life work. His reputation as a teacher and a master in this branch of medicine became world wide, and his text-book on the "Science and Art of Midwifery" was hailed as the best treatise on the subject that had ever been published. It has been translated into the French, Italian, and Spanish languages, and has recently been adopted as a text-book in the Medical School of London. The interesting style of the book, the clear exposition of the subject, and the rational and logical treatment therein set forth will signalize it as a classic for many generations.

Dr. Lusk was a pronounced conservative, indeed he was rather timid in his proving of new remedies and surgical procedures. In this respect he exerted a wholesome influence upon the profession, especially at times when waves of surgical epidemics threatened to obliterate all treatment save that by surgical means.

To those who knew him well, Dr. Lusk was a man of warm impulses, of strong attachments, of a sweet spirit, and a lovable nature. To his patients he was not only the man of science, but the warm and sympathetic friend, whose coming was always welcome, and whose words of sympathy accomplished their object for they were always genuine. His life was as open as a book. He always said what he felt and felt what he said. His words were devoid of diplomacy, and in his conduct finesse had no place.

Dr. Lusk leaves three daughters and two sons. The eldest son, Graham Lusk, is Professor of Physiology in Yale University. The younger son, Dr. W. C. Lusk, was associated with his father in his practice. He is Assistant Demonstrator of Anatomy in Bellevue Hospital Medical College, and Visiting Physician to the Workhouse and Almshouse on Blackwell's Island.

DR. J. LEWIS SMITH OF NEW YORK.

Dr. J. Lewis Smith died suddenly of apoplexy in the seventieth year of his age at his home in New York, June 9th. He was born in Onondaga County, New York, October 15th, 1827, his father being the Hon. Lewis Smith, a direct descendant of John Smith, one of the founders of the New Haven Colony. His early education was obtained in the public schools, which at that time were of an inferior grade. He prepared for college at the Cortland Academy of Homer, New York, one of the foremost preparatory schools of the country, and entered an advanced class of Yale College, graduating in the same class with President Timothy Dwight. He began the study of medicine with Dr. Caleb Green of Homer, N. Y., Professor of Materia Medica in the Geneva Medical College. He afterward became a student of the elder Austin Flint and Frank H. Hamilton of Buffalo, and attended a course of lectures in the Buffalo Medical College. In 1851 he came to New York, and was graduated from the College of Physicians and Surgeons in 1853. He located in practice in the same year, and was appointed Curator to the Nursery and Child's Hospital in Lexington Avenue, where he made his first studies in the pathology of the diseases of children. In 1854 he determined to make the diseases of children his special field of investigation and practice.

His first publication was entitled "A Review of Epidemic Smallpox as it Prevailed in New York City at Different Periods During the Last Fifty Years," *New York Journal of Medicine*, July, 1854. He was also the author of the following contributions: "Report of a Case of Hydrophobia, with Statistical Observations," *New York Journal of Medicine*, September, 1855, and continued in the same journal for January, March, and May, 1856; "Remittent Fever in Children," *New York Journal of Medicine*, January, 1857; "On Infantile Pneumonia," *New York Journal of Medicine*, March, 1857; "Post-Mortem Appearances in Eleven Cases of Cholera Infantum," *New York Journal of Medicine*, July, 1857. From this time until his death he contributed upward of one hundred papers to the various medical periodicals on diseases of children. He also made large contributions to the following works: Ziemssen's "Cyclopedia of Practice of Medicine," Ashhurst's "International Encyclopedia of Surgery," Starr's "Diseases of Children," Keating's "Cyclopedia of Children's Diseases," Sajous' "Annual," Pepper's "System of Practice of Medicine," "Reference Hand-Book," etc.

He held the following appointments: Curator to the Nursery and Child's Hospital, Physician to the Northwestern Dispensary, Visiting Physician to the New York Infant Asylum, Visiting Physician to the Charity Hospital, Visiting Physician to the Infant Asylum on Randall's Island, Visiting Physician to the New York Foundling Asylum, Consulting Physician to the Nursery and Child's Hospital, Second President of the American Pediatric Society, Professor of Diseases of Children in Bellevue Hospital Medical College.

The first edition of his work on "Diseases of Children" appeared in 1869, and since that date eight editions have been published at intervals varying from two to four years.

RESOLUTIONS ON THE DEATH OF DR. J. LEWIS SMITH.

June 11, 1897.

WHEREAS, The Medical Board of the New York Foundling Hospital has lost by death its oldest member, Dr. J. Lewis Smith, who for twenty-five years was Visiting Physician to the Institution, be it

Resolved, That it record this tribute to his memory:

His fame and faithfulness were ever devoted to the interests of this Institution.

Resolved, That this Board attend the funeral in a body; that a copy of these resolutions be spread upon the minutes and forwarded to the current medical periodicals, copies of the same being sent to the family of the deceased.

(Signed) JNO. J. REID, M.D., President.
W. P. NORTHRUP, M.D., Secretary.

ECHOES AND NEWS.

Enclosed Street Cars.—The New York Board of Health has passed an order requiring every street car line to run at least one enclosed car in every four.

Color of the Eye Indicative of Character.—One of the most curious results of the investigations made by doctors in the Russian jails is the statement that each group of criminals has its own peculiar color of the eye.

Leprosy in the Sandwich Islands.—Private advices from Honolulu report that leprosy is spreading with alarming rapidity in the islands. Formerly it was confined almost entirely to the natives, but now many whites are falling victims to the disease.

Vaccination and Tuberculosis.—The official *Reichsanzeiger* of Berlin published June 11th the decision of the Royal Scientific Medical Commission appointed to investigate the question whether vaccination against smallpox produces a disposition to tubercular disease. The commission finds there is no proof of such a disposition upon the part of vaccination against smallpox.

Meat Inspection in Rome, N. Y.—The Board of Health has adopted a rule requiring all persons selling meat to butchers in that city to have it inspected by the Meat and Milk Inspector, and marked with a white tag when first-class and with a red tag when second-class. A fine of not less than $10 is to be imposed for a failure to do this, and a similar fine imposed on butchers who expose meat for sale not properly marked. The rule takes effect at once, and the public is cautioned to see that the meat it buys is tagged.

Experts in Leprosy.—At the international leprosy conference to be held at Berlin on October 11th, Dr. Hutchinson of London will lecture upon alimentation and leprosy. Professor Virchow will discuss the pathologic anatomy of leprosy. Dr. Neisser of Breslau will deal with the origin of the disease, and Dr. Besnier of Paris will treat of its etiology. Professor Koch will discuss the question as to whether the disease is infectious. Drs. Kitasato of Tokio, Mauritz of Hawaii, During of Constantinople, and other eminent experts will attend.

New York Medical League.—A certificate of incorporation of the New York Medical League was filed with the Secretary of State at Albany, June 10. It proposes to unite fraternally physicians in good standing for mutual protection, and to advance the best interests of the medical profession. The trustees are Drs. Gustave Scheler, Douglas H. Stewart, E. Eliot Harris, John C. Schminck, Joseph E. Messenger, Frederick R. Sturgis, J. Smith Peterson, G. T. Harrison, Geo. D. McGauran, A. W. Warren, and Wm. J. Lamer of New York City.

Sending the Leper Back.—Mrs. Sansoni, the leper, who has caused so much trouble for Allegheny and Baltimore health officials, will be sent back to Allegheny in spite of that city's protest. It is said that the Baltimore officials are preparing a special car for her transportation. It will be a steel freight car, fitted up as comfortably as possible, and it is to be sealed until it reaches its destination. It is to be hoped that the international leprosy conference will settle the question of the communicability of leprosy. For a "non-infectious disease" it has already caused enough terror in the world.

Opening Day at Robin's Nest.—One of the most deserving of New York's many charities had its annual opening on the 12th inst. In addition to the many friends and patrons from the surrounding country—Tarrytown, Irvington, and Dobbs Ferry—several representative men from New York were present to lend encouragement, give statistics, and wish the young ladies, who so nobly support this charity, Godspeed. Thousands of little ones in New York are benefited annually by the work of the Robin's Nest. Children from St. John's Guild Hospital and Hospital for Ruptured and Crippled are cared for during the entire summer gratis.

Favorable Report on Diphtheria Antitoxin in London.—The report of the medical superintendents to the Metropolitan Asylums Board of London on the use of antitoxin in the treatment of diphtheria during the year 1896 has just been presented. It confirms and emphasizes the favorable conclusions reached in the previous year, when antitoxin was first used. The statistical results with regard to mortality are compared with those for 1894, the year immediately preceding the introduction of antitoxin and the one in which the lowest mortality had been recorded up to that time; they show a marked improvement in all classes of cases, and especially in the severer ones. The inferiority of the results obtained to those presented in the American Pediatric Society is attributed by the English medical periodicals to the inferiority and uncertainty of the antitoxin used.

Knives and Nails in a Man's Stomach.—An extraordinary case was recently reported from Vienna in which various household utensils were found on necropsy in the stomach of a woman. It is reported from Kansas City that a street performer known as the "Human Ostrich," who entertained his audiences by swallowing all sorts of articles, recently suffered so much from the effect of his last feat that he was obliged to submit to gastrotomy for relief. On opening the stomach the following articles were found: One four-bladed knife, 1½ inches long; one two-bladed Barlow knife, four inches long; one knife blade, 3¼ inches long; one knife blade, three inches long; two knife blades, each two inches long; one knife blade, one-inch long; thirty-two eight- and tenpenny fence nails and spikes; thirty-four sixpenny wire nails, sharp pointed; twenty-six shingle nails, each one-inch long; sixteen carpet tacks and small wire nails, one horseshoe nail, three large screws, one barbed-wire staple, and three ounces of fine glass. The man died two days later.

A New Hospital and Dispensary in New York.—There was filed at Albany, June 8th, with Secretary Hebbard of the State Board of Charities, an application for permission to incorporate the West Side Clinic and Hospital Association of New York City. The directors of the proposed hospital are Robert E. A. Borr, Charles G. Judson, S. F. Hayward, Robert Sherman, Drs. Louis A. Queen, Irving Townsend, George A. Shepard, Irving P. Sherman, H. S. Hathaway, F. M. Frazer, E. S. Munson, William H. Vanden Burg, and David Curtis of New York City, and Thomas E. Brown, Jr., of South Norwalk, Conn. In connection with the above announcement of application for incorporation it will be interesting to note what the action of the State Board of Charities will be in view of the fact that the west side of the city is already superabundantly supplied with clinics and dispensaries. It will be further interesting to observe the action of the various medical societies that have been organized for the purpose of curtailing the further growth of the free dispensary system.

The Prince of Wales and Antivivisection.—It is a well-known fact that the irrepressible and narrow-minded advocates of antivivisection have been endeavoring to dragoon the Prince of Wales into some admission that he would not sanction the expenditure of any of the money, collected in behalf of the hospital fund known by his name, upon those hospitals the staffs of which are alleged to perform experiments upon living animals. The Prince has avoided being drawn into the trap laid for him, and the antivivisectionists have taken umbrage and decided to work against the interests of the fund. In his recent speech at the opening of the new school buildings at Guy's Hospital the Prince said: "I have made careful inquiries and have every reason to believe that whenever experiments upon animals are performed in this school, they are undertaken with the object of promoting advances in medicine and surgery which are likely to be of benefit to suffering humanity, and I have satisfied myself that such experiments are conducted under strict supervision by highly qualified investigators, and that in practice the only operations performed upon animals which are not in a condition of complete anesthesia are inoculations and hypodermic injections."

CORRESPONDENCE.

THE INTERNATIONAL CONGRESS AT MOSCOW.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: The undersigned Chairman of the American National Committee, which was established at the request and under the authority of the General Committee of the Twelfth International Medical Congress, begs to inform the numerous gentlemen who are constantly applying for information concerning certificates, trips, fares, hotels, etc., that he has none to give, not having heard from the General Committee these two months.

Very respectfully,
(Signed) A. JACOBI, M.D.

NEW YORK, JUNE 14, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

NEW CLINICAL AMPHITHEATER OF THE MEDICO-CHIRURGICAL HOSPITAL—PHILADELPHIA COUNTY MEDICAL SOCIETY—PHILADELPHIA PATHOLOGICAL SOCIETY—GRADUATION EXERCISES OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

PHILADELPHIA, June 12, 1897.

THE construction of elaborate operating-rooms by the hospitals of Philadelphia has of late become so common that it arouses but passing attention, unless one of these structures happens to be of a particularly elaborate nature, involving a large expenditure of money, and the embodiment of many extremely advanced ideas. A building of this kind, for it has cost a large sum to erect, and certainly comprises every modern detail in its construction, is the one recently completed by the Medico-Chirurgical Hospital, which was open for inspection during the late meeting of the American Medical Association in this city. The exterior is in the Renaissance style of architecture, with a base of brownstone supporting a superstructure of terra cotta and Pompeiian brick. Marble tablets inscribed with the names of Hippocrates, Galen, and Celsus on the one hand, and of Lister, Pasteur, Koch, Agnew, Goodell, Pancoast, and Gross on the other are placed below the large arched windows of the front of the building.

The operating amphitheater, with rows of individual seats for five hundred students, is floored and wainscoated with marble, plastered with a thick enamel finish, and lighted by a large sky-light to the north. By means of a system of pipes encircling it, the whole room may be completely flooded with a large volume of water, which is carried off by ample drains at its base, Adjoining the arena are rooms for the storage and cleaning of instruments, for pressure sterilizers, for dressings, and for private operations. An important feature of the building is the heating and ventilating plant, insuring a free circulation of filtered fresh air, heated to any desired temperature, and, in the amphitheater, delivered through apertures beneath the students' seats, and removed through large exhaust ventilators. Taking the building either as a whole, or considering it in detail, it must strike the observer that the claims of its projectors and friends that it is the finest in the world must be regarded as substantiated.

The last stated meeting of the Philadelphia County Medical Society, held on June 9th, was devoted to the consideration of the treatment of high myopia; and two interesting papers on this subject were read, one by Dr. T. B. Schneideman, on "The Proposed Operative Treatment of High Myopia," and the other by Dr. Edward Jackson, on "The Treatment of Very High Myopia." Dr. Schneideman's paper dealt with the results claimed by various foreign ophthalmologists in removing the crystalline lens for the correction of this condition, and gave a succinct review of the opinions held by these operators. After discussing the faults and discomforts of concave lenses of high correction, and their impracticability for general use, he described the technic of the operation, and spoke of the good results attending this procedure, such as clear vision without a lens, improvement in visual acuity, cessation of the myopia, and restoration of binocular vision. Dr. Jackson's paper maintained that in the majority of cases of very high myopia the operative treatment should not be considered, and that the removal of the crystalline lens was not attended by such freedom from risk as the European operators claim. He advocated the use of high correcting glasses, and showed the fallacies in arguments against their employment, although admitting the field of usefulness of the operative treatment in a small number of cases in which other means of treatment prove inefficient. In closing, Dr. Jackson urged that the condition be prevented by early attention to the care of ordinary myopia.

In the joint discussion of these papers, Dr. W. L. Pyle explained that the very limited abilities of most Continental opticians in the mechanical execution of lenses probably would account for the preference of foreign ophthalmologists for the operative treatment of high myopia, rather that its correction by glasses, but that this condition did not exist in this country, thanks to the skill shown by American opticians. Dr. J. P. Thorington thought that in view of the personal equation which must enter into the consideration of every case of myopia, one could not arbitrarily recommend either a high or a low correction as the best treatment; but he preferred to employ full correction in cases not exceeding 6 D. Dr. S. Lewis Ziegler said that he would rather prescribe a full correction for distance, with a modification for the reading glass.

At the last meeting of the Philadelphia Pathological Society, held on June 10th, Dr. W. M. L. Coplin showed some interesting specimens, both gross and microscopic, from a case of cirrhosis of the liver, this organ being uniformly "hobnailed," extensively atrophied, and showing marked evidences of capsulitis; microscopically there were seen areas of inflammatory interlobular exudate, and signs of a probable septic infection. Dr. Coplin also showed specimens illustrating hepatic cirrhosis in a pig; the animal had been fed for a long time on buttermilk, which contained a small percentage of alcohol, and to this fact the speaker was inclined to attach a questionable etiologic import.

Dr. Joseph Sailer showed several specimens of degenerative changes in the nerve-cells, and described minutely the alterations in nucleolus and protoplasm constituting the condition. He took the ground that nerve-cell degeneration was not characteristic of any particular disease, but was only an evidence of some pathologic change.

A specimen of a kidney with double ureter was presented by Dr. Frank White, who detailed the history of the case, and demonstrated the pathologic condition.

Dr. J. Dutton Steele showed a tuberculous kidney, with involvement of the ureter down as far as the bladder, and infiltration of a part of the latter viscus. He was inclined to consider the case one of possible primary renal tuberculosis, although stating that the patient from whom the specimen was obtained also had a tuberculosis pneumonia, and old apical adhesions.

The graduating exercises of the Class of 1897 of the Medical Department of the University of Pennsylvania were held in the Academy of Music on June 9th, in conjunction with the other departments of the University. Dr. John Marshall, Dean of the Department of Medicine, conferred degrees upon 147 graduates—the largest class of all the departments; the Faculty Auxiliary to Medicine granted certificates to a number of others, who had completed courses in medical jurisprudence and other branches. A large number of prizes were awarded for general excellence, and for the best examinations in the various branches of medicine.

OUR VIENNA LETTER.

[From our Special Correspondent.]

THE EXISTENCE OF THE GERMAN UNIVERSITY OF PRAGUE THREATENED BY LEGAL REGULATIONS AS TO THE USE OF THE BOHEMIAN LANGUAGE—AN ATYPICAL CASE OF DIABETES—DIABETES AND THE INTERNATIONAL CONGRESS AT MOSCOW—TRACHOMA ENDEMIC IN MANY PARTS OF HUNGARY—A BULLET IN THE FEMUR FOR EIGHTEEN YEARS, AND CHRONIC LEAD POISONING.

VIENNA, May 24, 1897.

DURING April a law was passed by the Austrian legisture for the regulation of the language to be used in the transaction of business, official and legal, in Bohemia. In accordance with the temporizing, conciliatory spirit which has characterized the attitude of the central government in Austria toward the provinces since Count Taaffe's ministry, some ten years ago, the new law makes the use of Cjeckish or Bohemian obligatory in legal matters. This would be of no interest to the world in general, though it might be looked upon as a step backward in culture to further encourage the use of a Slav tongue where German is gradually acquiring supremacy, were it not that this law threatens to injure very seriously the German University of Prague.

As a concession to Bohemian National feeling about eight years ago a Bohemian University was established in that city, and this of course has taken many students from the German University. As the new law makes it necessary for anyone who holds an official position to know Bohemian, students from even German parts of the province will now find it advisable to pursue their studies in that language. The faculty of the German University, at a meeting held May 12th, signed a formal protest to the Imperial government declaring that this law, if enforced, will mean the practical annihilation of their University. As the German University of Prague is the oldest of the German universities in Europe, and has always been widely known for its broad scholarship and thorough, progressive, scientific spirit it seems too bad that it should be the victim of the narrow, short-sighted policy of a government which yields to party and sectional feeling without consideration for scientific progress.

The medical world would seriously miss the work which has been done at Prague if it were to be blotted out, and yet it is almost to be blotted out for the future if it is to be known only through the shadowy medium of the Cjeckish tongue, and such abstracts from it as may occasionally find their way into German. Good sense and better judgment will surely prevail in government councils and keep them from sinning so grieviously against progress as to look for the reintegration from narrow supposedly National feeling of a language which possesses no literature, and which practically shuts out those who employ it exclusively from the circle of European intercourse.

At the last meeting of the Vienna Medical Club Dr. Kolisch presented a very interesting atypical case of glycosura or diabetes. The patient, a girl of twenty, was passing urine which contained from five to eight per cent. of sugar. There was no doubt that this was grape sugar. The condition was accompanied by none of the usual symptoms of diabetes—no polyuria, no polydipsia, no loss of weight, or notable increase in appetite, and there was a general sense of well being, in marked contradiction to what might have been expected under the circumstances. Closer study of the cases only made the anomalous character of the glycosuria clearer. An absolute diet consisting only of fat and albuminous material did not cause the disappearance of sugar from the urine. Yet when the glycosuria was at its maximum no excess of sugar could be demonstrated in the blood. The urates were not increased in the urine at any time, and a careful examination of all excretions showed that metabolic processes were not using up more material than was ingested. The patient was in a good state of "nitrogenous equilibrium" with the balance slightly in her favor, so that the absence of the loss of weight, of polydipsia, and of bulimia was readily explained. There was absolute accretion of material rather than waste.

Dr. Kolisch is not sure that he may not have to do with a beginning genuine diabetes latens or insidiosus. Several such irregular types have been reported, but this case does not seem to conform to any of them. The absence of hyperglykemia, *i.e.*, increased amount of sugar in the blood at times when large amounts of sugar are being excreted would seem to indicate a sugar excretory function (or lesion ?) of the kidneys. For the series of symptoms observed in the case—glycosuria, without azoturia, polyuria, and hyperglykemia—the name "tachyglykuria" is suggested. The significance of the symptoms as was pointed out, is like that of many other metabolic anomalies, a mystery, and must remain so until a more thorough knowledge of organic functions will enable us to better understand metabolic processes generally.

With regard to diabetes, there seems to be nearly everywhere an air of expectancy as to what the very near future will reveal. Two of the men who in very recent years have added most to our knowledge of the disease, Lépine and Minkowsky, are to read papers on "Forms of Diabetes" at the International Congress at Moscow. The contributions are confidently expected to clear up some disputed points in the physiologico-pathologic groundwork of the disease, and especially to add to our knowledge of the causes and conditions obtaining in diabetic coma.

From Vienna some interesting developments in connection with diabetes, from the clinical and diagnostic standpoints, are looked for. That the symptom-complex of diabetes is not an anatomic or etiologic unity has long been conceded; that it is also not a clinical symptomatic unity is becoming clearer and clearer, though this has long been the accepted teaching. More exact diagnostic methods as to the urine and blood contents, not only as regards sugar, but especially for other abnormal materials are to be demonstrated, and the diagnosis of progress of the disease toward its fatal termination in coma made available for the practitioner for prophylactic purposes.

A recent official report from Hungary reveals the existence of a very unfortunate state of affairs there with regard to the contagious eye diseases. At the end of last year there were over 30,000 cases of trachoma in that country. The affection is practically endemic in certain of the lowland provinces, as Donan and Theiss, but has not spared even the high mountainous districts. Attention is called to the liability of contagion where men associate without proper precautions. As immigration in these later years have brought to the United States many of these people who huddle together in our mining regions without the simplest hygienic precautions, the necessity for watchfulness in the matter is evident. The germs of the disease are already present, and if the salubrious air of the Hungarian mountains, and the rugged health of the mountaineers, have not availed to protect them in their native land the gradual spread of the disease may be looked for under less favorable conditions with us.

The *Wiener Medicinische Zeitung* for May 18th contained an account of the removal of a bullet from a femur, which had been lodged there since the last Turkish war. The interest of the case lies in the fact that all the symptoms of chronic lead poisoning had developed, and absolutely nothing was effectual in relieving them until the bullet was removed. It had been in place for about nineteen years, and had given rise to a fistula which has been continually discharging pus from the very beginning. It was probably the persistent presence of these secretions that prevented the bullet from becoming encysted and brought about the continual absorption of sufficient quantities of lead to give rise to typical lead colic, the blue line on the gums, obstinate constipation, chronic indigestion, and serious anemia. All of these symptoms disappeared after the removal of the ball, and the patient now, two years after the operation, is in excellent general health. The number of cases on record of lead poisoning from the presence of bullets in the body is rather small, and they always seem to have been accompanied by the fistulous discharging condition that occurred in this case.

SURGICAL TREATMENT OF ULCER OF THE STOMACH—SURGICAL TREATMENT OF DIFFUSE PERITONITIS—USE OF MURPHY'S BUTTON IN GERMANY—NUTRITION AND INTESTINAL PUTREFACTION—PYELONEPHRITIS IN CHILDHOOD.

AT the twenty-sixth congress of the German Society of Surgery held in Berlin from April 21st to April 24th, V. LEUBE read a paper on *the surgical treatment of ulcer of the stomach.* By careful attention to the minutest details of non-operative treatment ninety-six per cent. of the cases of ulcer of the stomach can either be permanently cured or much improved. Less than two per cent. are treated without benefit. and two per cent. of the patients die. These figures are given as the result of experience with over a thousand cases treated by the author during the last ten years, by rest in bed for at least ten days; the application of poultices as hot as can be borne, the poultices being changed every ten minutes for ten days; the daily ingestion of lukewarm Carlsbad water, and the most carefully regulated diet for a period of some weeks.

Leube gives as indications for operation: (1) Small but continuous hemorrhages. (2) Pain and vomiting which the treatment above fails after several weeks to relieve. (3) Perigastritis as the result of adhesion, although the non-operative treatment is first to be tried. (4) Perforation into the abdominal cavity. As recovery in this complication is only possible when the stomach is empty, and is even then rare, operation should be performed immediately. Practically the same indications for operation were given by MIKULICZ: (1) When the life of the patient is threatened directly or indirectly by hemorrhage, perforation, or starvation. (2) When thorough medical treatment gives little or no result and the patient's pleasure in life is taken away by his suffering.

KOERTE warned against operation in cases of profuse hemorrhage. In one such case it was found that the ulcer had eaten into the pancreas and finally eroded the splenic artery. In another case the blood came from a branch of the pancreatico-duodenalis artery.

KOERTE discussed the *surgical treatment of diffuse peritonitis*, basing his conclusions upon a study of ninety-nine cases produced by disease of some organ; in which are not included cases of peritonitis after injury, strangulated hernia, or intestinal obstruction. Puerperal septicemia, carcinomatous, tuberculous, and chronic peritonitis are also excluded. Of these ninety-nine patients seventy-one were operated upon, of whom twenty-five, or thirty-five per cent., recovered. Of the remaining twenty-eight, some were too far gone for operation, while in six, it was not evident that there was any purulent effusion into the abdominal cavity, and the general condition of the patient gave hope of recovery without operation. All of these six patients recovered.

The object of operation is (1) the removal of the exudate in order to limit extension of the infection, and (2) the relief of the abdominal cavity from high pressure, the restoration of the activity of digestion, of the circulation, and of respiration.

Operative interference should be as rapid and as simple as possible. The chief object is the removal of the purulent exudate by irrigation with hot water or by sponging. An antiseptic solution must not be used. If there is a perforation in the stomach or duodenum, it should be closed. For perforations lower down, drainage alone may be used if the opening is not readily accessible to suture. Multiple counter openings are no longer advised.

In the after treatment the strength of the patient should be sustained by rectal injections, intravenous saline injections, and hypodermic stimulation. Gastric lavage and high enemata are also serviceable. Morphin, not opium, should be given to relieve pain.

KOENIG called attention to the fact that most cases of peritonitis following perforation of the appendix are not really cases of general peritonitis, but consist of one or more encapsulated foci of suppuration, while a part of the abdominal cavity remains intact. These, therefore, should not be described as cases of diffuse peritonitis.

ISRAEL, in order to reduce the virulence of the exudate, diminishes abdominal pressure as much as possible by a long crucial incision, which he leaves open. In this manner he has been able to decrease considerably the mortality in such cases.

MARWEDEL referred to the use of *Murphy's button in Czerny's clinic.* Fifty-five operations were performed with its aid. The results were in the main satisfactory, although in three cases the button failed to pass down the intestine, causing perforating peritonitis and death. Brentano, who collected records of 328 anastamoses with the button, found indication of cicatricial contraction in only three cases. Marwedel agrees with Murphy in considering a superimposed suture not only useless, but dangerous.

At the Union for Internal Medicine, session of April 12, 1897, ALBU, in discussing the subject of *nutrition and intestinal putrefaction*, said that no successful attempts to disinfect the intestine have as yet been made. The nearest approach to this is obtained by the use of laxatives, which remove bodily a great portion of the contents which are capable of putrefactive changes. The words "asepsis of the intestinal tract" are nothing more than a phrase, for neither by medication nor by the most thorough use of enemata can one free the intestine from bacteria or the urine from the absorbed products of their action. The flooding of the drug market with so-called intestinal antiseptics is calculated to disgust the serious physician with the use of therapeutic remedies.

At the session held May 3d, BAGINSKY spoke of *pyelonephritis in childhood*, a rare disease, of which he has seen, in one form, four cases. Its characteristic points are an intermittent fever with alternating subnormal and high temperatures, and the varying condition of the urine, which, sometimes, is perfectly clear, and at other times has a fixed sediment. The bacterium coli may be demonstrated in freshly voided urine. In this series of cases there was obstinate constipation, the fecal masses being wrapped in membrane.

In a second form of the disease, four cases of which Baginsky had also seen, the pyelonephritis follows upon a long-continued and wasting diarrhea. This form of the trouble usually ends fatally, and the kidney is found to contain, besides suppuration in the pelvis, small abscesses in the substance, while the tubules swarm with masses of bacterium coli, and may also contain other germs.

London.

VENEREAL TUMORS IN DOGS CONVEYED BY COITUS—RECTAL CONCRETION—RUPTURE OF THE HEART WITHOUT PERFORATION—NON-TUBERCULOUS POSTERIOR BASIC MENINGITIS IN INFANTS—A NOVEL CURE FOR EXTROPHIC BLADDER—TUBERCULOSIS AT AN ADVANCED AGE—RAW MEAT AND HOT WATER IN GOUT.

AT a meeting of the Pathological Society, held April 6th, SMITH and WASHBOURN described a series of *infective tumors occurring in the genitals of dogs*. A dog affected with a tumor on the penis served twelve bitches, of whom eleven became infected. Three of these bitches were then served by a second dog, who developed a growth on his penis. He in turn served two healthy bitches, one of whom he infected. By artificial inoculation a similar growth was produced on the penis of a healthy dog. The tumors commenced as minute papules, growing slowly and becoming at about the end of twelve months lobulated masses, which were easily removed from the underlying tissues, together with the mucous membrane to which they were attached. In one case there was infiltration of the muscular wall of the vagina, and in another the lymphatics of the groin were affected. There was nothing in the microscopic appearance of the tumors to distinguish them from human sarcomata. There was no tendency to spontaneous cure, but if removed at an early age, the tumors did not recur. In two cases the tumors were successfully transplanted, and developed growth in a manner similar to that already described by writers upon the infective nature of cancer.

CRIPPS exhibited a *concretion which he removed from the rectum of a woman aged sixty*, who for fifteen months had suffered from diarrhea, accompanied by fluid stools and mucous. The concretion was so large and hard that it was necessary to divide the anus backward in order to extract it. It weighed eight ounces, and was found to be composed entirely of fecal material.

At the session of May 4th, FOX exhibited the *heart of a stout woman aged sixty-nine which was ruptured, but not perforated.* The patient was seized with precardial pain after a cold bath. Morphin and venesection gave some relief, but forty-eight hours later, after making a slight movement, she suddenly died. The pericardium was found to be filled with blood, and there were two small rents in the left ventricle which did not extend through the whole thickness of the heart's wall. It appeared that the distention of the fatty heart had ruptured the exocardium and some muscular fibers, causing the escape of blood into the pericardium, and death followed forty-eight hours later.

Before the Royal Medical and Chirurgical Society, April 13th, CARR read a paper on *non-tuberculous posterior basic meningitis in infants.* This is a distinct form which has not up to the present time received adequate recognition. It mainly affects the posterior portion of the base of the brain, but is entirely independent of tuberculous meningitis. It runs a subacute or chronic course with fairly characteristic symptoms during life, and has constant and definite *post-mortem* appearances. Carr has seen eleven cases, all occurring in healthy infants under one year old. The onset was sometimes slow, sometimes not so gradual, but in all there were severe vomiting, retraction of the head, and stupor passing into coma, which lasted usually several weeks. The cases all terminated fatally in from five weeks to three months.

At autopsy, inflammation of the pia was found over a definite area at the base of the brain, hydrocephalus, and in some cases closure of the opening between the fourth ventricle and the subarachnoid space. In no instance was there any sign of tuberculous disease in the cranial cavity or elsewhere, and its possible connections with injury, diseases of the ear, congenital syphilis, and epidemic cerebrospinal meningitis were considered and abandoned. In two cases the lateral ventricles were tapped; in one instance with marked benefit. In two other cases trephining proved quickly fatal owing to too rapid escape of the fluid.

At a meeting of the Medical Society held April 11th, HARRISON showed *a boy of fifteen years with extrophy of the bladder, whose right ureter had been brought out through a lumbar incision*, the left kidney previously having been removed. The operation was completely successful. The urine which flowed from the wound was clear and showed no tendency to form phosphatic deposits, and did not irritate the skin.

At the session held April 26th, MARSH called attention to the fact that *tuberculosis in old people is by no means as rare* as a perusal of the text-books would lead one to suppose. He mentioned three cases of Pott's disease with abscess within his own experience in patients aged sixty-nine, seventy, and seventy-four. Other tuberculous lesions which he had seen in the seventh and eighth decades were tuberculosis of the bones and joints, tubercular epididymitis, and tuberculosis of the cervical axillary glands.

ARMSTRONG pointed out the *advantages of an exclusive meat diet in certain cases of chronic gout.* By giving patients nothing but red meat and hot water, it is possible to obtain rapid diminution of abdominal girth, loss of fat and flabby tissue, an increase in the quantity of the urine, and the ultimate disappearance of urates, alkaloids, and toxins from the urine.

At the meeting of the Clinical Society, held April 9th, MARSH described a *sarcoma of the prostate in a patient aged fifty-seven.* The mass grew to be so large that it interfered with defecation. A colotomy was performed, but the patient died. At autopsy the tumor, which measured seven and one-half by four and one-half inches, was found to have displaced the bladder and filled the pelvis. Microscopically, the tumor was a spindle-celled sarcoma.

JOHNSON reported a case in which *axial rotation of a pedicle of an ovarian cyst was met with in a child of five years of age.* Operation was performed, and an uneventful recovery followed.

At the meeting held April 23d, MARSH showed a case of *hydronephrosis in which the collection of fluid was found to be between the kidney and its capsule.* Nothing in the history of the case or in the condition of the parts at operation indicated the cause of the hydronephroses.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

The Semicentennial Meeting, Held at Philadelphia, June 1, 2, 3, and 4, 1897.

SECTION ON PRACTICE OF MEDICINE.

(Continued from page 805.)

THIRD DAY—JUNE 3D.

THE first paper read at the morning session, entitled

SOME OF THE CLINICAL USES OF THE X-RAYS IN MEDICINE

was presented by DR. F. H. WILLIAMS of Boston. During the past year he had had more than 500 cases in which he had used the X-rays, and he had never seen any harm or inconvenience follow its use. His conclusions regarding the results attained by the use of the X-rays were as follows: The normal brightness of the chest is increased in pneumothorax and emphysema, and markedly decreased in tuberculosis and pneumonia. Obscure cases of aneurism can be diagnosed, and pericardial effusion be distinguished from enlarged heart. In tuberculosis and pneumonia the excursion of the diaphragm is limited, while in pneumothorax and emphysema its position is much lower than normal. The normal outlines of the organs may be changed by the presence of abscesses and new growths. The fluoroscope gives evidence of returning health, and more early information as to the advent of pneumonia and tuberculosis. It furnishes the easiest way to ascertain the amount of fluid in the pleural or pericardial sac and shows the amount of displacement of the heart, and in diseases of the heart it is especially serviceable. In some cases the diagnosis can be made by the use of the X-rays alone. As an aid to diagnosis it is in daily use in the Boston City Hospital as an adjunct to the stethoscope. In all cases of doubt the first X-ray examination should be checked by a second. The Crookes' tube should be about two or three feet away from the patient as the shadow on the screen will be too large if the tube is placed closer.

DR. C. L. LEONARD of Philadelphia read a paper on the same subject, entitled

THE APPLICATION OF THE ROENTGEN RAYS TO MEDICAL DIAGNOSIS.

The rays promise to be of especial value in medicine, for they eliminate the factor of personal equation in diagnosis, and replace the mental picture which a physician forms of the condition of internal organs from a physical examination with the more exact skiagraph. The application of these rays to medicine is attended by very many more difficulties than their application to surgery, for in medicine it is necessary to deal with substances the opacity of which is not marked. The stomach, not being opaque and hence not discernible in a skiagraph, means have to be adopted to make it so, and this is accomplished by injecting into it an emulsion of bismuth which coats the walls and renders the organ more opaque than the pelvic bones. Opacity, as used in Roentgen-ray nomenclature, is merely a relative term.

TUBERCULOSIS ANTITOXIN

was the title of a paper read by DR. E. A. DESCHWEINITZ of the Biochemical Laboratory of the Department of Agriculture, Washington. His efforts had been directed toward the production of an antitoxin serum, and his experience had been gained wholly by experimentation upon animals. He had tried injections of tuberculin and also of an antituberculous substance, and of combinations of both. He had found that tuberculin, when injected into horses and cows, produces a substance in the serum which, when injected into animals, protects them from a fatal dose of attenuated tuberculosis germs, or retards their development. But in order to produce this antituberculous substance (whatever it might be) a great deal of time is required, and some of his animals have been under observation for several years, and their serum does not seem to protect animals from tuberculosis any better than it did at first. An antitoxic substance can be produced, but as yet it is small in amount. He hoped that a satisfactory antitoxic substance will soon be obtained, but as yet the treatment is in the experimental stages.

A paper on the same lines, entitled

ANTITUBERCULIN

was read by DR. J. MCFARLAND of Philadelphia.

DR. D. L. ROCHESTER of Buffalo read

A REPORT ON THE TREATMENT OF TUBERCULOSIS.

He had used Edson's aseptolin and Paquin's antitubercle serum, but had not obtained satisfactory results with either. All the patients whom he had treated had bacilli in the sputum, thus confirming the diagnosis of tuberculosis. Aseptolin had been tried for four to six months, and was followed by a subsidence of the sweating, a gain in weight, and an increase of appetite, but the local conditions did not change. The cough and expectoration also were lessened. Four of the patients treated with aseptolin died, one, he believed, because of the treatment, and in no case was there a cure. The improvement noted continued during warm weather while the patients were able to be out of doors, but ceased when cold weather returned. It was true that the sweating was checked, but as this result could be equally well obtained in other and less dangerous ways there was no excuse for using the treatment for this purpose. Paquin's antitubercle serum is worse than useless, for it not only produced no good results, but it caused acute pain at the seat of the injection and produced a severe urticaria. The most satisfactory substance he had yet obtained for the treatment of tuberculosis was the nuclein prepared by Bonn of Ann Arbor. He had yet to see a case in which it did not aid the cure. He had seen some cases in which there had been a cure while taking nuclein, and in all there was improvement.

The conclusions he had reached from his investigations were that nuclein does no harm if the injections are not too rapidly increased; that the injections are not painful. He had seen cases recover, that is, that all signs of the cavity in one lung had disappeared, and in one case the bacilli had disappeared. Another case might also be reported as cured, as the patient felt so well that he neglected treatment. Whatever the form of specific treatment adopted, plenty of exercise should be taken. The treatment should begin by keeping the upper air passages clear. For the dyspnea, which is so frequent, fluid extract of quebracho is the best remedy. For the fever nothing is needed beside the nuclein. Sponging should be persisted in. Sweating will generally disappear with the use of the nuclein, but if not, atropin and aromatic sulphuric acid are the best remedies. For anemia bone marrow should be given.

A FURTHER REPORT ON THE TREATMENT OF TUBERCULOSIS BY IODOFORM INUNCTIONS

was the title of a paper, read by request, by DR. L. F. FLICK of Philadelphia. He now uses europhen instead of iodoform and the result is equally good, while the treatment is much less offensive. Ten cases were reported in the first series as having been treated, and of these one patient was reported as apparently being well, three as approaching a cure, four in which the disease was arrested, and two in which there had been a relapse and the patients were doing badly. It was now eight years since he began treating tuberculosis by this method, and he had now a number of additional cases to report. Of the ten first reported, eight had since died, one was apparently well, and one had disappeared from observation. Of the eight patients who had died, seven had succumbed to tuberculosis and the other to some abdominal trouble, so that the best results he could claim for the treatment was ten per cent. of cures. Of five additional cases hitherto reported three patients had died, one was well, and one had disappeared from observation. Of fifteen patients, eleven had died, two were well, and two had disappeared. Of the two who had disappeared one probably had died and the other probably had recovered. This gave twenty per cent. of recoveries. More recent statistics gave practically the same results. It was unfair, he said, to draw conclusions in regard to a treatment of tuberculosis carried on such a short time, Unless it has stood the test of a number of years it is unsafe to place a remedy upon the list of curative agents.

At the afternoon session the first paper read was by DR. E. B. BORLAND of Pittsburg, entitled

CURABILITY OF PULMONARY TUBERCULOSIS.

Scientific physicians, he said, in the treatment of tuberculosis, should make use of the light which still shines clearly instead of following after false ones. Tuberculosis may be considered a curable disease if treated early and properly, but when it has once impregnated the system nothing is known which can eradicate it. He does not believe in the theory of immunity, for if there were anything in this doctrine the child of an immune mother should be entirely free from all danger, which experience has not shown to be the case. The question then arises: Can tuberculosis be cured; and if so, by what means? If latent tuberculosis is to be cured it must be taken in hand early, but unfortunately this is seldom done at the present day. Nature frequently produces cures of tuberculosis in man, and physicians should endeavor to copy Nature's methods. Among the most essential of her remedies is dry air, but he thinks that altitude probably has little to do with the cure, though it is certainly true that in high altitudes the unused air-cells are called into activity and developed. The condition of the excretory organs should be attended to. Woolen clothing aids the excretory processes, while cotton clothing checks it. Nature clothes all her animals in wool, and only foolish man insists upon wearing cotton fiber. Cod-liver oil and antiseptic inhalations should be used when indicated.

The average life of seventy-seven per cent. of tuberculous patients may be set down as being two years. Strict sanitary methods should be adopted to prevent the spread of the disease. If everybody could be prevented from spitting on the sidewalk, it would do more to prevent the spread of tuberculosis than all of Koch's tuberculin. To-day physicians are lying supinely upon their backs hugging the delusive phantom of a specific instead of making use of the methods of treatment already at hand.

DR. DENNISON of Colorado said that he wished especially to endorse the statement of Dr. McFarland as to what tuberculosis really is. Since there had been some adverse opinions expressed as to the views contained in the papers of Drs. McFarland and Rochester, he wished to say that they were in line with his experiences in Colorado. First of all, he entered a protest against Dr. Cohen's statement, that seeking after a specific for tuberculosis is like searching after a will-o'-the-wisp, and he desired to commend the good work done in this country by Klebs, Trudeau, and Von Ruck in their search for an antitoxin. It seemed almost impossible to him that anything can be proved by using tuberculin on healthy persons, and clinical experience is necessary to test the virtue of any antitoxin which might be obtained. The argument advanced that there is such general infection of the human race with tuberculosis that a certain amount of antitoxin must be present in the blood of all individuals, or all would die, had no bearing on the question of antitoxin. The immunity of tuberculosis is merely a relative immunity. This is to be obtained by building up the individual cells, thereby increasing the powers of resistance. He had used antiphthisin with some success, and he did not think these good results were due entirely to the climate of Colorado, as had been suggested. Of course this climate is a factor in the cure, and altitude is an important element, notwithstanding the assertions of Dr. Borland to the contrary. Rarefaction, of the air, as found in Colorado, leads to increased pulmonary exercise. As to artificial immunity against tuberculosis, he hoped that the time will soon come when this will be rendered possible by the discovery of the right antitoxin. He believed that this exists somewhere in tuberculin. It might be in Koch's new remedy, which is made from an extract of the live bacilli. But somewhere there is an antitoxin in the bacilli which, if given in the proper doses, will produce an immunity. He believed that Klebs and Von Ruck are coming nearer and nearer to the solution of the question every day.

DR. KLEBS said there are two methods of great importance in the search for an antitoxin; one is work in the laboratory and the other is clinical work, and these should be entirely distinct. He had been sorry to hear it said that the search for an antitoxin is a chase after a myth, for he believed that to be a very dangerous doctrine. A belief in such a doctrine will put a stop to all investigation. Animal experimentation is necessary, and by proving in this way that tuberculosis in animals is curable the clinician has something to go on. In the study of tuberculosis a long period of observation is necessary, and this can best be obtained in the laboratory. The remedy must be tried there before it can be subjected to clinical tests.

An important thing in the treatment of tuberculosis is the hygienic management of the case. Hygiene is the most important factor in the treatment of tuberculosis, but it is likely to fail of its purposes because it is impossible to get every one to carry out the details for any length of time, and continued perseverance in one direction is the one essential thing in the treatment of the disease. To enforce hygienic rules it is necessary to have the means of carrying them out. This has been best accomplished in this country by Trudeau, who stands foremost in the treatment of tuberculosis at his sanatarium in the Adirondacks. Patients are there put through the strictest hygienic training, with the result that when they leave, after about a year's residence, they go out into the world knowing how to prevent the spread of the disease. For this work institutional treatment is necessary, and the State can do more in that direction than individuals. If the Association would take this matter up and urge its importance upon public opinion much good might be accomplished.

DR. ALLEN expressed the belief that the tubercle bacilli exists in the inflammations, and that the proper mode of treatment consists in a destruction of the pabulum on which they grow and develop. It seems to be the preconceived idea in some minds that all who believe in a specific treatment for tuberculosis should avoid dietetic and hygienic treatment, but this is not so. He had employed Paquin's serum to some extent, and one patient had recovered. There is not a single bacillus in the sputum at the present time, whereas formerly they were very plentiful. The man is now doing hard work, and is improving every day. Two other patients have been very much improved, but in one there has been such a destruction of tissue that a cure is out of the question. If patients with tuberculosis are taken in hand promptly and treated with creosote and cod-liver oil and sent to a suitable climate, like that of Colorado, he believed they can be cured.

DR. J. N. UPSHUR of Richmond said that an essential factor in the development of tuberculosis is malnutrition. In the South this lesson has been taught by the experience of the negro. Before the war it was a rare thing to see tuberculosis in the negro. Scrofula was common, but the tubercles did not develop in the lungs. This was due to the fact that at that time the negroes lived largely in the open air of the country and had plenty of nourishing food. Since the war all these conditions have changed. The negroes have migrated to the cities where they live in conditions of squalor and overcrowding, and frequently with not enough to eat, subsisting largely on decayed vegetables and over ripe watermelons. These are conditions tending to malnutrition, and here tuberculosis is found to be increasing at a very rapid rate. The lesson to be drawn from these conditions is that on account of malnutrition tuberculosis of every kind is rife among these people.

DR. GEORGE M. STERNBERG of Washington said he was very much surprised to hear the talk about the doctrine of the infectiousness of tuberculosis. The infectiousness of the disease can be demonstrated by these gentlemen upon themselves at any time if they care to do it. We cannot have tuberculosis without the presence of the tubercle bacillus, but something more than this is wanted, the susceptibility of the individual. This susceptibility depends upon family characteristics, insufficiency of diet, anemia from any cause, and upon other conditions. Another point is that there is a certain amount of antitoxic substance in every individual which can be overcome, and this overcoming of the antitoxin depended upon two factors, *viz.*, the virulence of the tubercle bacilli and the size of the dose. It has been found, for example, that a small number of bacteria may not give rise to the disease in an individual, while a larger dose will produce it, so that people who live in places where there is a large amount of dried expectoration in the air are more likely to take the disease than those living in a sparsely settled and healthy locality. There are other factors also which act as exciting causes to an existing predisposition. Such a condition is dust which irritates the lungs and leads to a chronic inflammatory condition of the mucous membranes.

Dr. James Tyson of Philadelphia stated that as one who had made use of Dr. McFarland's antituberculin he wished to say a few words in regard to his experience with it. He was glad to learn that a search is being made for an antituberculin, but his experience with that produced up to this time has been absolutely negative, owing, perhaps, to the short time he has been experimenting with it. Even in that short time, however, he has experienced the greatest difficulty in persuading patients to take the remedy. What with urticaria and painful arms the patients have been nearly in a state of rebellion, and he was almost glad when the supply of antituberculin had been used up. He hoped that those who were working on these lines would discover some other method of administering the medicine than by the hypodermic syringe, and thus do away with one of the greatest drawbacks to the use of the serum.

Dr. Paul Paquin of St. Louis said that it is evident that every one engaged in the search for a tubercle antitoxin is convinced that tuberculosis is such a mixed malady that we must depend for its cure upon remedies of different kinds, and he agreed with those who believed that no one remedy can cure tuberculosis in every form. He doubted whether a specific for all forms of tuberculosis, pure or mixed, will ever be found. Certain forms of tuberculosis, however, will recover in spite of the doctor. We must acknowledge that Nature can cure tuberculosis, and we should endeavor to adopt her methods. If we reflect on the results obtained in other maladies by the use of antitoxins we will be justified in trying to imitate Nature in her cure of tuberculosis.

Dr. McFarland said that Dr. Tyson's experience with his antituberculin agreed with that of Dr. Wilson so far as the urticaria was concerned, and he thought it was due to the fact that the serum was too fresh. It had been said that tuberculosis is a disease which might get well of itself. Nobody doubted that, and laboratory workers are trying to find out *why* it gets well and *how* it gets well, so that they may copy Nature's methods. It is a fact which he could not explain, but for which he was very sorry, that laboratory workers have not the sympathy and help of the clinician. As a matter of fact the laboratory worker is the clinician's best friend.

Dr. de Schweinitz, in closing, said that tuberculin is a solution of some of the products of the germs, but is not a solution of all the germs, because some of the metabolic products are destroyed. For this reason tuberculin cannot have the same effect as if the live bodies of the germs themselves were injected into the body.

Dr. Rochester said he was glad to find that all recognize the fact that malnutrition is one of the serious conditions predisposing to tuberculosis. While not a laboratory worker himself, he wished to make a severe criticism of the attack that had been made on the laboratory worker. For any man to disparage the work of laboratory men is utterly unjustifiable. For the past ten or fifteen years all the greatest advances in medicine have been made by the laboratory worker. He felt that he should apologize for having mentioned a preparation that has been advertised in the way that aseptolin has, and he thought that the profession should not use remedies advertised in this way. He had used it only at the earnest request of his patients. The urticaria which Dr. Tyson complained of in the use of antituberculin was similar to that which he had met with in the use of Paquin's serum. Bonn's nuclein was not an antitoxin, but he had obtained results from its use which he had not been able to get with any other remedy.

Dr. Flick said that his treatment with iodoform and europhen is in line with that by antituberculin, and if it were possible to keep patients immune to the development ot new foci the disease might he cured. If it were not for auto-intoxication patients might get well.

Dr. Borland said he had not meant to cast any reflections upon the work of the bacteriologist. He valued the work of the laboratory man as highly as any, and he would be the last to disparage experiments which might lead to a method of producing immunity.

After the closure of this series of papers and discussions upon tuberculosis, a paper was read by Dr. Woods Hutchinson of Buffalo upon

SOME DEFORMITIES OF THE CHEST IN THE LIGHT OF ITS ANCESTRY AND DEVELOPMENT.

He divides all chests roughly into the quadrupedal chest, or dog-form, and the flat chest, or human form. The first is the primitive chest, produced by going upon all fours so that the only direction for expansion is anteriorly, while the flat chest was developed when primitive man became a climbing animal. The flat chest of the bat, due to the drawing up of the scapulæ by the action of the wings, was at one time supposed to place this animal in the same class with man instead of with rats. From a large number of measurements he has reached the conclusion that the familiar flat chest of consumptives is not flat at all, but, if he might make use of a Hibernianism, appears to be flat because it is so round. In other words, he believes it is a reversion toward the ancestral type, and that the chest approaches so nearly the round or quadrupedal form that the scapulæ have a tendency to slip off the shoulders when the person assumes a stooping attitude. The reason why tuberculosis attacks the lungs more frequently than any other organ of the body, according to the author of the paper, is because the lung is the organ of the least resistance, and the reason for this is that it is the youngest portion of the body from a biologic point of view.

The next paper, upon the

MANAGEMENT AND TREATMENT OF MALIGNANT TYPES OF CROUPOUS PNEUMONIA,

was read by Dr. D. S. Campbell of Detroit. He advocates the expectant plan of treatment, and called attention to the necessity of taking care of the heart in every way as this is the organ that is chiefly attacked. The fever should be combatted by cold applications. From this plan of treatment he has obtained good results, both in hospital and private practice. The mainstay in his treatment was the cold bath.

As a striking contrast to the main feature in Dr. Campbell's paper, the use of cold water, **DR. J. EICHBERG** of Cincinnati then presented a paper upon

THE HOT BATH IN THE TREATMENT OF PNEUMONIA.

The average temperature of the bath in his practice is 100° F., but it varies within a range of 95° in mild attacks to 110° F. in acute cases. The duration of the bath is ten minutes, and after being taken out the patients are wrapped in a warm, dry blanket, without previous drying, and put to bed, and after an hour are briskly rubbed. At first he had used the hot bath only for its antipyretic action, and had given it only when the temperature reached 103° F., but later he began giving the bath as a routine treatment irrespective of the height of the temperature. The bath is repeated every three hours, and he believes it is a powerful adjunct in the treatment of pneumonia. Strong evidence of the comforting effects of the bath is found in the fact that patients invariably ask for its repetition. It relieves all the distressing symptoms, especially the dyspnea. Respiration becomes slower, the temperature falls, delirium subsides, and many of the patients seem to void a larger quantity of urine. The pulse becomes slow, but only in the same proportion that the respiration becomes slower. The hot bath has the effect of "letting blood without losing it." In the treatment of his cases in this way he allowed the patient a full, nourishing diet. Drugs are not neglected, and he gives digitalis and strychnin as indications require. The hot bath may be given to patients of any age, the last patient he treated in this way being seventy-three years old. Cold cloths may be laid on the head and face during the administration of the bath, if desirable. Five or six baths a day are given during the febrile period, and one or two a day afterward. In his experience with this treatment seventy-four patients have recovered and nineteen have died. Six died suddenly on the second and third days.

CHEYNE-STOKES' RESPIRATION

was the title of the next paper, read by **DR. N. S. DAVIS, JR.**, of Chicago. His attention had been directed to this subject some time ago, and in looking into it he was struck by the meager amount of literature relating to it. Cheyne-Stokes' respiration has been observed as an accompaniment of many disorders, and can be produced artificially. It occurs most frequently in cerebral affections, but has also been seen in hemaphilia, in hemorrhage after operations, whooping cough, croupous pneumonia, and after tracheotomy. It occurs most frequently as a complication of chronic renal disorders. It seems to be the normal method of respiration among some animals during hibernation.

DR. H. B. ALLYN of Philadelphia read a paper upon

MULTIPLE NEURITIS IN INFLUENZA,

in which he stated that the great majority of cases are of toxic origin. The term "neuritis" was used for convenience. The milder type of influenza is more likely to give rise to neuritis than the severer forms. He believes that the poison of influenza is a frequent cause of attacks of neuritis and multiple neuritis. The difference between neuralgia and neuritis is one of degree rather than of kind, and he thinks that a great many cases reported as neuralgia really are neuritis.

A CASE OF ACUTE LYMPHATIC LEUKEMIA WITH STREPTOCOCCUS INFECTION

was the title of a paper read by **DR. J. B. HERRICK** of Chicago. This case, which resulted fatally, was not allowed to go to autopsy, but a quantity of blood was taken from the heart immediately after death, and experiments made with it confirmed the diagnosis, and blood obtained from the finger two days before death showed streptococci. The question arose whether it was not a streptococcus disease with leukemic complications.

The next paper read was entitled

CHRONIC INFLAMMATION AND ULCERATION OF THE DUODENUM, WITH RESULTANT REFLEXES,

by **DR. J. M. ALTEN** of Kansas City, Mo. He stated that the disease is more common in women than in men because of the greater reflexes in the former, and occurs most frequently between the ages of twenty and forty years. It is frequently the result of typhoid fever, exanthemata, burns, etc. Inflammation of the duodenum will produce inflammation of the skin. It has long been a well-known fact that gastric disturbances cause insanity, but it has never been known why they do so. Epilepsy is also caused by reflexes, and a large number are the result of reflexes due to inflammation of the duodenum. He believes, also, that ulcer of the stomach is frequently the result of extension of ulcers of the duodenum, and that the latter are very much more common than the former. The treatment consists in keeping the organs at rest, and in maintaining the nutrition of the patient, resorting to rectal alimentation when necessary.

REVIEWS.

THE MULTUM IN PARVO REFERENCE AND DOSE BOOK. By C. HENRI LEONARD, M.A., M.D., Professor of the Medical and Surgical Diseases of Women, Detroit College of Medicine. Detroit: The Illustrated Journal Co., Publishers, 1896.

THIS is a new and enlarged edition of the Dose Book, printed and bound in a handy manner for the pocket. It gives the doses of over three thousand preparations, and also contains tables of poisons and antidotes, the solubility of drugs, abbreviations, urinary tests, schedule of fees, etc. It is a convenient and useful book of its kind.

ORGAN DISEASES OF WOMEN AND STERILITY CURABLE BY MEDICINES. By J. COMPTON BURNETT, M.D. Philadelphia: Boericke & Tafel, 1897.

HE who believes that displacements of the uterus may be corrected by the internal administration of high potencies of *Thuja occidentalis*, should read this poorly printed book. Those who cannot bring themselves to such a faith, will simply marvel that such stuff can be written at the present day.

LAW OF REFRACTION-CHANGE FOLLOWING INCREASE OR DECREASE OF BODY-WEIGHT.[1]

BY GEORGE M. GOULD, M.D.,
OF PHILADELPHIA.

IN starvation, ninety-seven per cent. of the fat of the body is lost before death, and of the remaining three per cent. the orbits always retain some and a larger amount proportionately than other localities. This seems to indicate that the cushion of fat blanketing the eyeball posteriorly is of great importance to the function of vision, and if so, it would appear natural that great increase or decrease of body-weight, consisting mostly in gain or loss of fat, might lead to changes of fat-deposits in the orbit, with consequent variations in pressure upon the eyeball. If to this consideration we add the noteworthy fact that a variation so small as that of one millimeter in the anteroposterior diameter of the eyeball produces the huge ametropic change of three diopters, we recognize how slight a difference in orbital pressure is required to account for a marked variation of refractive error. It is easily demonstrable that a difference of one or two diopters may be produced simply by increase or decrease of posterior pressure, without posterior staphyloma or in any way altering the total capacity of the eyeball, but simply by altering its shape. The equatorial diameter would be lengthened by a slight polar shortening, and *vice-versa*. The ametropia of albinotic eyes shows this fact produced by another mechanism.

These purely *a priori* thoughts had been in mind for years, and I had had a number of patients in whom changes of refraction were suspected to be coincident or consequent upon changes in body-weight, but there were always some elements of doubt, due to the fact that as the patients had been previously examined by other oculists, I might reasonably suspect they were errors due to my own carelessness, etc. Last spring, however, several cases came nearly together, and a study of the case-records appeared to warrant a tentative theory, or working hypothesis, of sufficient plausibility to justify making the suggestion public. I remember to have been often perplexed before the present suggestion occurred to me to account for decreases in myopia. I, by no means, claim any great definiteness of result or any precise formulation of a law, except in general terms, and liable to modifications and exceptions. I myself have had one or two cases showing that, if founded upon fact, the rule is not invariable. It certainly could not be so, because many complicating conditions and circumstances must occur and must be taken into account. With all due allowances and justifiable cautions it seems to me that the thought is a reasonable one, and is given in order to be proved or disproved by the future observations of many. If it is true it will help to explain a number of perplexing cases, and put us and our patients on guard. I am sure the common belief that myopia does not lessen is frequently disproved by facts. It has for years been my custom to expect refraction-changes consequent upon severe general illness, and it may be that these are, at least in part, mere corollaries of the theory under consideration.

In brief my suggestion is as follows: Great increase of body-weight may cause shortening of the anteroposterior diameter of the eyeball or alterations of curvature (increase of hyperopia, decrease of myopia, or similar changes of astigmatism); and on the other hand, great decrease of body-weight may be coincident with lengthening of the eyeball (decrease of hyperopia, increase of myopia, or like changes of astigmatism).

A few cases[1] clinically illustrating this law, if it may be so called, are as follows:

Case 3125.—The patient was a man of twenty-five, and was first examined March 11, 1894, with the following finding:

R.—Cyl. 0.25 ax. 20°; L.—Sph. 5.50—Cyl. 0.50 ax. 160°. On March 22, 1897, I again tested the error, finding: R.+Cyl. 0.37 ax. 105°; L.—Sph. 4.75=Cyl. 0.25 ax. 160°.

Since the first examination he had gained about thirty pounds in weight, and the refraction-changes were in the right eye 0.62 D., and in the left 1.25 D. The case seems noteworthy because the change was twice as great in the highly myopic eye.

Case 4034.—The patient was a man of thirty-two, and was examined in 1889 by an oculist whose record I can trust, and who prescribed:

R.—Sph. 4.00—Cyl. 1.00 ax. 165°; L.—Sph. 1.25—Cyl. 1.00 ax. 90°. In 1895 I found: R.—Sph. 3.50=Cyl. 1.00 ax. 160°; L.—Cyl. 2.50 ax.

---

[1] Read at the Thirty-third Annual Meeting of the American Ophthalmological Society, held at Washington, D. C., May 4, 5, and 6, 1897.

[1] All, of course, tested under mydriasis.

90°. On March 24, 1896, I found: R.—Sph. 2.75 —Cyl. 1.25 ax. 180°; L.—Cyl. 2.25 ax. 90°.

During these seven years the patient had steadily gained in weight a total of about forty pounds. In this case it was the highly myopic eye that had decreased in myopia a total of at least one diopter, the left remaining comparatively unchanged.

Case 1493.—A woman of twenty-five was refracted in 1891, and the following error was found: R.—Sph. 5.50=Cyl. 1.00 ax. 5°; L.—Sph. 5.50 —Cyl. 1.00 ax. 5°. In 1887 the error was found to be: R.—Sph. 4.75—Cyl. 1.12 ax. 5°; L.—Sph. 4.75—Cyl. 1.37 ax. 5°.

In the meantime she had gained about thirty pounds in weight, the coincident loss of myopia being about 0.50 D.

Case 4280.—Miss. B., eighteen years of age, was refracted April 18, 1896, and found to have the following error of refraction:

R.—Sph. 0.24+Cyl. 0.50 ax. 75°; L.—Sph. 0.25+Cyl. 0.62 ax. 105°. On April 24, 1897, the refraction was found to be as follows: R.+Sph. 0.50+Cyl. 0.50 ax. 75°; L.+Sph. 0.25+Cyl. 0.75 ax. 90°.

During the year she had gained very much in health and flesh, but just how much the increase in weight was it is impossible to say.

Case 4074.—A boy of thirteen was first refracted in November, 1895. At this time he was of normal height, but very fat, weighing about 150 pounds. On February 19, 1897, he returned, complaining that he could not see the blackboard and other distant objects as plainly as formerly. Upon inquiry, the mother said that these complaints had been growing more frequent and more pronounced during the past two or three months, during which hygiene and dietary measures had been enforced to reduce his flesh. The treatment had been so successful that during this time he had lost about fifty pounds in body-weight, and in girth the waist had fallen from 39½ inches to 34½ inches. At the same time his height had decidely increased, the lessening of fat having been followed by a rapid gain in body-length. (There is considerable indefiniteness as to the weight and height, but I secured from his tailor the waistband measurements.)

His refraction in 1895 was:

R. and L. the same+Sph. 0.25+Cyl. 0.75 ax. 90°. Fifteen months later it was: R.—Sph. 0.25 —Cyl. 0.75 ax. 180°; L.—Sph. 0.25—Cyl. 0.87 ax. 180°.

Thus there was a total change of refraction of fully two diopters accurately synchronous, with the loss of flesh. Up to the time of "going to press" there has been no noteworthy change in refraction, though I have re-examined the eyes several times.

I could cite other cases apparently of the same kind, but these seem sufficiently illustrative of the theory suggested to stimulate the observation of others. It is also possible that changes in muscle-balance may sometimes depend upon the amount of fat in the orbits and lids. An indirect but striking proof of the theory set forth consists in the fact of the production of high degrees of compound hyperopic astigmatism in albinos due to the continuous lid-pressure. The albino seeks to shut out light by the lids, and the pressure lessens the anteroposterior diameter of the cornea and shortens the vertical meridian to an enormous degree.

EXCISION OF THE HIP.[1]

By WISNER R. TOWNSEND, M.D.,
OF NEW YORK;
PROFESSOR OF ORTHOPEDIC SURGERY IN THE NEW YORK POLYCLINIC; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

To determine the exact value of any particular method of treatment in chronic disease of the hip-joint is a difficult matter. Each case varies, and statistics and the conclusions drawn from a series of cases are often misleading. I will not attempt to gather together a vast number of figures, therefore, or to quote from other authorities, but simply to report the results of the operation of excision in the patients on whom it has been performed from 1886 to 1896, inclusive, in the Hospital for Ruptured and Crippled, New York. This work has been made possible for me by the kind assistance of Dr. W. J. Reynolds, late House Surgeon of the Hospital, who made an abstract of the histories as given in the record books of the institution, to which has been added the final results in all cases, when these could be traced. Personally, I have had the opportunity of witnessing all but two or three of the operations, and of making the final notes.

Following the plan of most American surgeons, the large majority of patients with hip disease at this hospital have been treated by means of the various forms of hip-splints in common use to-day. An endeavor is made to treat each case strictly on its merits, and the treatment is by no means a matter of mere routine. The patients first make application to the Out-Patient Department, and if the disease is just beginning, a plaster-of-Paris spica bandage is applied, which, in mild cases, is kept on until a splint is made ready, or, if the child needs hospital care, until it is admitted to the wards. If the symptoms are acute, the child is put to bed and a weight and pulley applied, with the object of overcoming the spasm and the deformity. When much deformity exists, hip-splints are not applied until this has been overcome. The patients applying for treatment all come from the poorer walks of life, and the home care in most cases is very inadequate. Many lack proper food, the hygienic surroundings are bad, and the necessary attention for the proper adjustment of the brace and its care are wanting and we cannot expect as good results as when the patient can be properly cared for at all times. In many instances when first seen the disease was far advanced and abscesses, sinuses, and marked general tuberculosis, with or without septicemia, were present. The general vitality was low, and in some an enlarged liver and spleen indicated that amyloid changes had occurred.

---

[1] Read before the American Orthopedic Association at Washington, D. C., May 6, 1897.

From 1888 to 1896, 2295 patients with hip disease applied for treatment at the hospital, and during the same time 121 excisions were performed on 119 patients. This clearly shows what a small proportion were subjected to the operation, and explains the position that has been given to excision in the treatment of hip-joint disease in this institution. In no case was excision practised except with the view of saving life. In many instances it was a *dernier ressort;* in others, it was to stop excessive drain from prolonged suppuration, to check amyloid changes, or to clean out and drain septic abscesses. Excision was never practised in the first stage of the disease, save in one case of double hip disease, and all but six cases were complicated by an abscess or sinus. The operation was resorted to only when other methods of treatment had apparently failed, and when it was believed that if some operation were not performed death inevitably would soon result. In some patients the previous treatment had been careful, thorough, and scientific, but the progress of the disease was not checked and excision was resorted to, while in others neglect and poor treatment rendered the operation necessary. From the fact previously mentioned, that these patients in many instances did not have proper home care, no inference can be drawn as to the value of the different forms of splints used during the previous treatment, or as to the value of aspiration of abscesses or injection of iodoform and oil as tending to render an excision necessary. In fact, quite a number of the patients were transferred from the Out-Patient Department to the hospital wards because their parents systematically neglected them and much of the benefit from the brace treatment was entirely lost, and no doubt in some positive harm was done.

In considering the ages of the patients, it must be stated that the hospital treats in the in-patient department only those children who are between the ages of four and fourteen, and a very few cases over the hospital age-limit were referred to other institutions for operation. The total number of patients operated upon, including those referred to other institutions, does not exceed five per cent. of the total number of cases seen, and this represents the most severe examples.

Abscesses or sinuses, much more often septic than non-septic, were present in 113 patients out of 119, and this emphasizes the importance of proper treatment of this complication. This subject has been thoroughly discussed of late years, and the fact clearly established that a cold abscess should be opened, thoroughly curetted, and properly drained whenever it becomes septic. Had this been done in every instance, the number of excisions would have been smaller. In the large majority, the patients were suffering from sepsis before the operation was performed, and naturally this also affected the ultimate result.

From a study of these cases the conclusion is inevitable that in a great many the fatal result was due more to sepsis than to tuberculosis. In many cases, the osteomyelitis present, and the deep burrowing of the abscesses, rendered perfect drainage almost impossible either before or after the operation. The number of cases of hip disease where abscesses were present but not infected, or when infected were promptly opened and properly drained, proved also that sepsis is responsible for the result. Much more than five per cent. of all patients with hip disease develop abscesses and yet make a good recovery and never suffer from general sepsis.

In ten per cent. of the cases there was marked osteomyelitis present, and in these the difficulty of perfect drainage is always great. In several instances counter openings were made lower down in the shaft of the bone and gauze drains passed into the medullary canal, but when this complication exists, and the patient has in addition much bony destruction of the joins from tuberculosis, I believe amputation at the hip-joint will give better results than excision; certainly the results in the cases the writer has had the opportunity to observe have been anything but encouraging. The shock accompanying an amputation will undoubtedly be greater than that resulting from an excision, but the cause of the sepsis will at once be done away with, and if the shock is not too serious there will be some chance of the patient's recovery.

The duration of the hip disease at the time of the operation in about seventy per cent. of the cases was from one to three years, and as the patients were all in the third stage of the disease the figures are such as we would expect. Careful inquiry was made in every instance to determine if possible the cause of the disease, and in six per cent. it was ascribed to a fall, a very small percentage, if we are to believe some authorities. In two instances children were subjected to osteotomy for the relief of the flexion deformity after hip-joint disease, and sepsis occurred and excision was subsequently done.

The acetabulum was involved in about ten per cent. of the cases and it was usually impossible to determine before the operation whether or not this bone was diseased. In but one case was there found complete bony ankylosis of the femur to the pelvis. In one case the head of the femur was found loose as a sequestrum in the joint, and in several others portions of loose bone were present, but in the majority more or less complete destruction of the head of the femur had taken place. Two children were subjected to excision of both hips, in one case both operations being performed at one sitting, and in the other after an interval of about a year. Both subsequently died.

The total number of operations was 121, the total number of patients, as has been said, being 119, 78 were males, and 41 females. The right hip was removed in 69 operations, the left in 52. In 24 the anterior incision was made use of and in 97 the posterior. In cases of the kind here reported, no typical operation can be performed. The incision is made so as to open the abscess or follow up a sinus, but our preference is for the posterior incision. The operations were performed under ether anesthesia except in three cases, when nitrous oxid gas was used. The plan was always to operate rapidly, remove the diseased tissues as thoroughly as possible, and to stop all hemorrhage promptly either by ligature or pressure. The wound was thoroughly packed with iodoform gauze, and in the earlier cases a plaster-of-Paris spica bandage was applied to keep the limb in proper position. The latter procedure has not been carried out for the last four years as it was feared that the wet plaster enveloping the child might have been responsible for some of the deaths from shock, and it also delayed getting the patient back to bed as it was necessary for the plaster to set before removing the child from the operating-table. A long side splint is now used instead of the plaster, and a weight and pulley is applied to the limb to make proper traction. These can be applied after the child has been returned to bed.

The subsequent care of the wound consists in dressing it every second or third day in order to secure proper drainage, to prevent absorption of pus, if it is septic, and to promote healing by granulation from the bottom. The attempts to sew up the wound in these cases have proved failures and no matter how carefully the operation is performed it is almost impossible to obtain primary union when marked sepsis is present. The incision wounds are sometimes very slow in closing and sinuses may persist even for years. The average time for the closing of the wound in the cases that have done well has not been less than six months. Various solutions have been used to encourage healing, but washing with peroxid of hydrogen and the application of balsam of Peru and olive oil have given the best results. Occasionally sinuses have been curetted and stimulating applications have been made to them.

Of the 121 excisions it has been possible to trace but 101. Of the 99 patients traced, 52 are known to be dead; and these include the 2 cases in which both hips were removed. Of these 52 deaths, 51 were attributable to the diseased condition present, and one to accidental drowning. In the latter case the hip had recovered and was in good condition at the time of death. The cause of death in 28 was exhaustion; in 9, shock, and in 9 tuberculous meningitis. The other causes were uremia, edema of the lungs, tuberculous peritonitis 1 each, and heart failure, 2. Exhaustion was responsible for over fifty per cent. of the fatalities, and this includes all cases of amyloid degeneration, besides those cases in which general tuberculosis developed. Long-continued suppuration and the weakening effects of sepsis helped to make this the most frequent cause. Of the cases of meningitis, in only one instance could the operation be held responsible for its development. In this patient the symptoms appeared twelve days after the excision, while in the others the period was much later, and the operation probably neither delayed nor hastened the fatal termination. These figures show that meningitis was the cause of death in ten per cent. of the cases traced.

Of the fatal results, 37 occurred within six months after the operation, and 10 more within one year. In 9 cases of shock death occurred within 48 hours. That more patients did not die from shock is due, I believe, to the rapidity of operating, to the small amount of anesthetic used, and to the subsequent faithful and efficient care of the house staff and nurses. The mortality rate in this series of cases is thus seen to be about fifty-two per cent., and when the condition of many of those operated upon is considered it is evident that no other result could be expected.

Of the patients traced, 47 are living; and of this number 26 are cured of the disease with varying amounts of shortening and with varying degrees of deformity. The latter in most cases is slight. The shortening depends upon the amount of bone originally removed, and upon the time that has elapsed since the operation. The fact that the upper epiphysis of the femur is removed, and that its presence is responsible for part of the growth of the limb easily accounts for the fact that in 3 cases seen six years after operation, the average shortening was 3.16 inches. In 4 patients seen five years after operation it was 2.68 inches, while in those observed during two years or less it was 1 inch. The shortening is not of great consequence, providing the limb is straight and in good position. When much flexion deformity is present, we usually also find more or less adduction, and this is a serious matter. In 10 patients the limb was extended to 180°; in 6, to 170° or over; in 7, to 165°, and in 6, to 160°. These 29 may be said to have the limb in a position that makes locomotion easy and are cured without flexion deformity. All beyond this have flexion and some lordosis as a result. The amount of motion in the joint varies; in 1 it is 130°, in 3 the limb can be brought to a right angle (90° of motion), 6 have from 30 to 40°, 8 have from 5 to 30°, and in 26 there is no motion. It was not possible to measure the degree of motion or the angle of greatest extension in every case, hence these data are missing in a few cases.

Of the 47 patients known to be living, we have found 26 cured. Of the remaining 21, fully one-half are in bad condition and will die from exhaustion if not from other causes, as the result of long-continued suppuration. Of this number, in 2 the sinuses are still discharging six years after the operation, in 1 after five years, in 2 after four years, in 1 after three years, and in 2 after two years. In the remaining cases, too little time has elapsed since the excision was done to allow of a final report being made. The results may be stated as 26 cures after 101 operations, and we have reason to believe that of the patients not traced many are living. To save only one patient out of every four operated upon, while not brilliant, shows that some good has been done, for these were all desperate cases, and we believe the patients would have died had the operation not been performed.

Whether amputation will save more lives in the same number of cases remains to be seen. Excision, to prove of benefit in a large percentage of cases, must be done early, and then the question is, Are we justified in operating early, knowing the good results to be obtained from mechanical treatment? The majority will answer in the negative, or in favor of the treatment by means of the various hip-splints now in use; and as our knowledge in their application increases and the general practitioner learns to interpret the early symptoms more promptly, so will the necessity for excision diminish.

Results in 121 excisions of the hip, performed on 119 patients at the Hospital for Ruptured and Crippled, New York, 1888 to 1896 inclusive: Of this number, Dr. V. P. Gibney performed 100, Dr. W. R. Townsend performed 15, Dr. W. J. Reynolds performed 3, Dr. Royal Whitman performed 1, Dr. W. B. Thompson performed 1, Dr. W. R. Martin performed 1.

A summary of the cases here reported is as follows: Total number of patients operated upon, 119; total number of excisions of the hip-joint, 121—males, 78; females, 41. Right hip, 69; Left hip, 52. Due to a fall, 20. Cause unknown, 101. Anterior incision, 24; posterior incision, 97.

Ages at time of operation: Three years, 1; four years, 12; five years, 13; six years, 17; seven years, 15; eight years, 16; nine years, 14; ten years, 13; eleven years, 8; twelve years, 6; thirteen years, 2; fourteen years, 3; fifteen years, 1.

Acetabulum involved in 18; of this number, 10 are living, 6 are dead, and 2 cannot be traced. Marked osteomyelitis present in 10. Duration of disease before operation: In 1 case, two weeks; in 1 case, three months; in 2 cases, six months; in 3 cases, eight months; in 41 cases, one year; in 37 cases, two years; in 13 cases, three years; in 6 cases, four years; in 5 cases, five years; in 2 cases, six years; in 3 cases, seven years, and in 7 cases the time is unknown.

Abscesses or sinuses were present in 113 cases, no abscess in 8, and double hip disease in 3. Both hips were excised in 2 cases; hip and spinal disease in 5, hip and knee disease in 2, hip and tarsal disease in 2. The hip, pubes, and ilium were involved in 1 case, the hips and pubes in 1, and the hip, sacrum, and coccyx in 1. Disease developed after Gant's operation of osteotomy in 2 cases, the head of the femur was loose in the acetabulum in 1, and syphilis was present in 1.

Cases operated upon in 1888, 3; in 1889, 1; in 1890, 6; in 1891, 22 (cured, 3); in 1892, 16 (cured, 4); in 1893, 13 (cured, 3); in 1894, 15 (cured, 0); in 1895, 17 (cured, 7); in 1896, 28 (cured, 9). Cases noted six years after operation have the following shortening: Four inches in 1 case, 3 inches in 1, and 2½ in 1; average, 3$\frac{1}{16}$ inches.

Five years after operation: four inches in 1 case, 3 in 1, 2½ in 1, and 1¼ in 1. Average, 2.68 inches.

Four years after operation: 2¾ inches in 1 case, 2½ in 1, 1½ in 2, and 1¼ in 1. Average, 1.6 inches.

Three years after operation: 1½ inches in 1 case, 1 in 1, ¾ in 2. Average, 1.08 inches.

Sinuses exist after operation for six years in 2 cases, 5 in 1, 4 in 2, 3 in 1, 2 in 2, and 1 in 12. Deaths, 52. From exhaustion, 28; shock, 9.

Tuberculous meningitis, 9. Developed twelve days after operation in 1 case; 1½ months in 1, 2 in 2, 2½ in 1, 3 in 1, 5 in 2, and 14 in 2. From acute uremia, 1; odema of lungs, 1; tuberculous peritonitis developed four months after operation, 1; heart failure, 2; drowning, nearly two years after operation, 1, Death occurred within six months of operation in 37 cases, 1 year in 10, 2 years in 3, and 5 years in 2.

CLINICAL MEMORANDA.

TWO CASES OF SYPHILITIC DISEASE OF THE LIVER.[1]

BY GEORGE L. COLE, M.D.,
OF LOS ANGELES, CAL.

I BELIEVE that some cases of syphilitic disease of the liver are mistaken for ordinary cirrhosis or for certain other obscure diseases of this organ and that some lives might be saved by appropriate treatment, which otherwise would succumb to the disease. My conclusion in this respect is based upon one or possibly two cases treated for cirrhosis of the liver (or for Bright's disease) by several competent practitioners, the patients having fallen into my hands when death seemed inevitable, and having been rescued by large doses of potassium iodid, and by mercurial injections and inunctions continued over a long period of time. In the case of one of these patients I accidentally discovered a syphilitic history which had been withheld from the former physicians in attendance, and this fact, together with the true picture of cirrhosis which the case presented, rendered completely pardonable the mistaken diagnosis which had been made.

The majority of text-books on practice either omit this subject entirely or dismiss it so briefly that our attention is not sufficiently drawn to it. Loomis, in his "Practical Medicine," devotes two pages to the subject, but under the head of "Gummy Tumor of the Liver," Osler devotes a page and a half to it, and among other things says that "the patient is anemic and passes large quantities of pale urine containing albumin and tube casts." Flint gives the subject a portion of one page, in which he says "it is usually accompanied by some or all of the ordinary symptoms of cirrhosis, and while not common it is one of the most frequent forms of visceral syphilis." Wood dismisses it with one short paragraph, while Strumpell devotes a page and a half to it, and begins his paragraph on treatment with this clause: "Whether we feel certain of syphilitic hepatitis, or merely suspect it, specific treatment should be tried." The cases which I wish to report are the following:

CASE I.—Male, aged forty-five, single; good family history. During the past ten years has been a heavy drinker, taking whisky straight and regularly rather than periodically. He denies all history of venereal trouble other than gonorrhea, but has lead a dissipated sexual life for many years. On September 6, 1893, I found him confined to bed. There was considerable edema of the lower extremities, and the abdomen was distended by fluid. The heart was normal, and analysis of the urine showed neither albumin nor casts. Paracentesis abdominalis had been performed three times previous to this date. On the 17th of September I drew off the fluid from the abdomen, when a careful examination showed the presence of a slightly enlarged liver, but further than this I was not able to determine anything characteristic of cirrhosis.

Thinking I had a typical case of hepatic cirrhosis to deal with, I treated him in accordance with this theory and interdicted the use of alcohol. Finding that he could tolerate large quantities of potassium iodid I prescribed it in dram doses three times daily with small doses of mercurials. During the three months following my first visit I drew off the abdominal fluid six times, removing two gallons each time. During the latter part of this period he wore an elastic abdominal supporter and the fluid accumulated more slowly. He began to gain strength and flesh and to resume his usual avocation, not forgetting in spite of my protests to return to his old convivial habits. He continued to take the iodid regularly and did well, although drinking heavily. The fluid formation ceased entirely and he went on to perfect health for many months.

On November 1, 1894, I was summoned at midnight, not having seen him professionally for nearly a year, and found him suffering from a very severe gastric hemorrhage. He was prostrated several days from this, but in ten days was up again, drinking as before. He has gone on to the present time without any further trouble. The fact of his speedy and complete relief, with no tendency toward a return of his former condition, notwithstanding the continued use of alcohol, and the want of evidence to show an established collateral circulation, has led me to believe this a case of specific disease of the liver. Other than the course of the disease, together with the tolerance of large doses of the iodids and of mercury, there is no *positive* evidence of syphilis.

CASE II.—Male, aged forty-four, father of two healthy children, aged four and seven years. When I first saw him, April 7, 1891, he had been confined to his room for three months, most of this time being unable to leave his bed. His sickness, however, had extended over a period of two years, and was ushered in by colicky pains in the hepatic region and gradual loss of flesh. I found him greatly emaciated, the feet and whole lower extremities edematous, and the abdomen distended by fluid.

There was considerable dyspnea from fluid in the pleural cavities. Examination of the heart and lungs did not reveal anything abnormal. I could not procure urine for examination but elicited the fact that some weeks previously he had been catheterized several times without result, and later on had passed large quantities of urine of such a character that a diagnosis of Bright's disease had been made and treatment had been carried out in this direction for several weeks.

Examination of the hepatic region was unsatisfactory on account of the ascites and hydrothorax. He denied any venereal history. He had been tapped twice within the month previous to my first visit. A specimen of urine was obtained on the following day, but on examination did not reveal the presence of albumin, sugar, or casts. On the 9th, two days after first seeing him, I drew off ten quarts of ascitic fluid, when examination of the hepatic region showed what seem to be a typical hobnailed liver, except that the surface projecting below the ribs seemed more markedly uneven than in any case I had previously seen. He had been taking a pill which he said contained mercury and this I had him continue, with the addition of potassium iodid in small and increasing doses. A few days later he informed me that about fifteen years before he had had a sore on his penis, which had healed so rapidly, without any further symptoms, that he did not suppose it could possibly be syphilis or could have any connection in any way with his present illness. Soon after I met the physician who had treated him years previously, and he informed me that the patient had had a true chancre at that time.

---

[1] Read before the California State Medical Society, April 1, 1897.

During the following five months the abdomen was tapped at intervals of from ten days to two weeks, and during this time mercurial inunctions and hypodermic injections of albuminate of mercury were given alternately, and the iodid was increased to about two hundred grains daily. He soon began to gain in strength and flesh, the time between tappings was increased, and an elastic abdominal supporter was applied. After the thirty-fifth tapping, which occurred on June 30, 1892, about fifteen months after the first removal of fluid from the abdomen, he gradually resumed work and is well to-day. He has continued to take the iodids intermittently and is apparently in as good health as ever.

ADDUCTOR VOCAL PARALYSIS.

By LEWIS S. SOMERS, M.D.,
OF PHILADELPHIA.

PARALYSIS of the intrinsic muscles of the larynx may result from a central lesion situated at the roots of the spinal accessory nerves in the floor of the fourth ventricle; from peripheral lesions, or may be due to changes in the structure of the muscles themselves. The laryngeal muscles may be affected in groups, or more rarely, individually. Probably the most frequent cause of adductor vocal paralysis, especially in females, is hysteria. The following case is reported on account of the absence of hysteria in the patient and for the reason that the etiology was somewhat obscure, the paralysis occurring after pneumonia. The history is as follows:

F. W., female, aged twenty-five years, single, occupation singer and music reader. Was first seen November 3d, 1896. Family history negative. She had had measles when a child; at five years she was said to have had "walking typhoid," and was sick for six months. Subject to headache on excitement for a number of years and also has sick headache when riding in the cars. She is a well-developed, robust, educated woman, and has been strong and healthy since childhood until the early part of December, 1895, at which time when walking with a friend he fell dead. This shock caused a general nervous condition (neurasthenia) of three-weeks' duration, at the end of which period she developed pneumonia, involving the left lung, being very ill for six weeks.

During convalescence from the pulmonary trouble she noticed that her speaking voice was not as strong as before, and was easily fatigued and became husky. On attempting to sing soprano she found it impossible, as she could not produce the notes, and she then placed herself under a physician's care for the vocal paralysis, but without results. At this time her general condition was good, although she was slightly nervous and suffered from a moderate degree of bronchial irritation, this subacute bronchitis being especially annoying at night. At irregular intervals attacks would occur resembling those of croup, and on several occasions it became necessary to call in medical assistance.

When I first saw the patient she was nervous and worried, as her singing was necessary in gaining her livelihood. She complained, in addition to the loss of her singing voice, of a tickling and dryness of the throat, of "catching cold" easily, and of hoarseness, and had a dry, irregular cough. Digestion was not normal, as she sometimes, though rarely, vomited after a full meal. She was moderately constipated, and felt bloated after eating, the tongue being coated, although her appetite was good. Headache was often present, and was most marked in the occipital and temporal regions. She slept well. The heart and lungs, with the exception of the slight bronchitis, were normal; the reflexes were normal, as was menstruation.

On examination of the upper respiratory tract the Schneiderian mucous membrane, especially over the middle and inferior turbinals, was found to be congested, and a moderate degree of turbinal hypertrophy was present. The pharynx was slightly sclerotic, and the lingual tonsil on the left side hypertrophied, while the faucial tonsils and postnasal space were normal. The larynx was plainly visible with the aid of the laryngoscope, the upper two rings of the trachea being easily distinguishable. The epiglottis and mucous membrane of the larynx were normal. The laryngeal and faucial reflexes did not differ from the normal, as the sensibility was not altered. The vocal cords were widely separated, being at an equal distance from the median line on both sides, the arytenoid attachment of the cords being the most characteristic feature, as they were widely apart. Motion of the cords was *nil* on respiration, and only by severe effort could movement be effected on phonation. The cords were normal in color, concave in appearance, and somewhat flabby.

The treatment consisted of deep inhalations of compound tincture of benzoin in albolene, and the interrupted electric current twice a week. The faradic current was applied by placing one electrode over the thyroid cartilage, and the other at some indifferent point. The duration of local treatment was from five to ten minutes at each *séance*. In addition to the local applications, the patient received one-sixtieth of a grain of sulphate of strychnin three times a day, the dose gradually being increased until she received one-tenth of a grain per day. Phosphate of soda as a laxative was directed to be used as indicated. Improvement of the vocal condition was gradual, the lateral arytenoids responding first, until the 8th of December, when she was decidedly better, the only changes from normal being the remaining paralysis of the arytenoid muscle. At this date the singing voice was nearly normal, slight fatigue after much use of the voice and some inability to reach high notes still being present. On January 5, 1897, the patient had not received local treatment or strychnin for more than two weeks, yet had been able to sing four solos during one day with but little laryngeal fatigue, and said that she never felt better physically. Except for some slight outward rotation and separation of the arytenoid cartilages the larynx was normal.

The total absence of any hysteric element in the case, as corroborated by Dr. Henry P. Boyer, opened up some interesting questions regarding the etiology of the paralysis, and also the location of the diseased tissue or tissues. It is a question whether the lesion was central or peripheral (in the spinal accessory or recurrent laryngeal nerves), or located in the affected muscles themselves. The absence of general or laryngeal evidences of any of the stigmata of hysteria at once eliminated that factor from the etiology, as in hysteria the cords while apparently paralyzed on phonation are freely movable during respiration. Cough is usually present in the hysteric form, but generally absent in true paralysis, although it may be present. As a general rule, it may be said that if adductor vocal paralysis comes on suddenly in a healthy woman and is intermittent, it probably is hysteric in origin. These cases frequently coexist with some disorder of the genital apparatus.

The elimination of disease of the nerve-centers or of the vagus, with the spinal accessory, becomes of importance, as treatment will be influenced greatly by the cause of the laryngeal paralysis. When there is localized disease of the brain or of the nerves already mentioned, other portions of the body besides the larynx are implicated, and the history of the case will generally point to some lesion either of the nerve-tissues directly, or, as is usually the case, pressure symptoms will be present. As the superior laryngeal is generally considered to be the sensory nerve of the larynx, and the inferior or recurrent nerve the one of motion, we could readily eliminate disease of the former as a cause by absence of interference with sensation, the laryngeal sensibility in this patient, as before said, being normal. The recurrent laryngeal nerves may be affected as the result of pressure, as from an enlarged thyroid gland, or by changes in their structure. Usually but one nerve is affected as the result of organic changes, more rarely both are involved. Cases have been observed in which the separate peripheral filaments of the laryngeal nerves have undergone morbid alterations producing paralysis of the different intrinsic muscles of the larynx.

The diagnosis in this case lay between peripheral changes in the inferior laryngeal nerves and alterations in the structure of the muscles involved. Morbid changes of the muscles without involvement of the nerve-fibers has been observed in rheumatism, progressive muscular atrophy and typhoid fever, in some cases the musculature being affected without apparent cause, and giving rise to a so-called idiopathic form. It seems impossible without a microscopic study of the nerves or muscles involved to make an accurate diagnosis, but from the history of the case and a careful study of the larynx, it seems possible that there was some pathologic change in the muscles.

The remaining question, as regards the causal relation of the pneumonia to the vocal paralysis, is rendered difficult of solution, as the former element of shock (caused by the sudden death of a friend as related in the history of the case) must be taken into consideration. This shock was followed by a period of nervous prostration of three-weeks' duration, this in turn preceding the attack of pneumonia, which latter lasted for six weeks. During this time her vocal apparatus was in perfect order, as shown by a normal speaking and singing voice, which did not become affected until late during convalesence from the pneumonia. For this reason, and further as the adductor muscles have in cases reported been affected during convalescence from severe diseases and during catarrhal inflammations, the evidence seems in favor of the paralysis being the direct result of the pulmonary changes, possibly being remotely influenced by the powerful nervous shock which she had received.

This form of laryngeal paralysis occurs most frequently in women, and especially in singers or those making prolonged use of the voice. The subject, in addition to vocal fatigue or partial loss of voice, usually complains of a foreign-body sensation referred to the larynx, and the well-known symptom complex of acute or subacute laryngitis is present. The respiration is normal, but phonation is difficult or impossible. In addition to the local affection, symptoms of anemiă or chlorosis are often present. The prognosis is favorable; although the paralysis may have existed for a number of years, cure may be effected, but the condition yields slowly and relapses are very apt to occur.

The treatment must be directed to the larynx, although it is important that the general health be maintained. Stimulating inhalations and the application of the galvanic or faradic current to the larynx, usually intralaryngeal (but in some cases the electricity may be used externally over the region of the larynx), will give the best results. Strychnin is of much value, and unless there are well-marked indications preventing, should be used in increasing doses in all cases.

The Delayed Effects of Frost-Bite.—General A. W. Greely, Chief of the Signal Corps of the United States Army, the Arctic explorer, has recently undergone an operation for the removal of the second finger of his right hand. Both hands of the explorer were frost-bitten in the Arctic regions, and although healing had apparently occurred, caries of the bone recently set in, necessitating the operation. It is said that the condition has been aggravated by the constant handshaking to which he has been subjected.

An Epidemic of Scarlet Fever Due to Milk Supply.—An outbreak of scarlet fever at Plainfield, N. J., has been traced by the Board of Health to the milk suppy furnished by a wholesale dealer. One of the employees, who was ill with scarlet fever, continued to assist in handling the milk. Under the supervision of a health inspector five hundred quarts of milk were seized and dumped into the sewer. The infected employee has been quarantined.

NEW INSTRUMENT.

THE MICROMOTOSCOPE.

By ROBERT L. WATKINS, M.D.,
OF NEW YORK.

FOR more than a year I have been trying in various ways to present living microscopic objects on a screen. After overcoming various obstacles, it was found possible to do this directly by the use of a special arc light in connection with the microscope. The one great obstacle—heat—was still present. This dried the specimens so promptly that the living objects were killed and the method had to be abandoned. The appearance of the vitascope, however, suggested the possibility of applying some such method to the studies I was pursuing. This proved a perfect success. By means of this instrument I discovered that the active motion of living microscopic objects could be readily photographed. By using from 50 to 150 feet of the vitascopic film, and taking a series of impressions in sufficiently rapid succession, I have been able to secure pictures which when passed through a lantern at the same rate of speed will present on a screen all the motions of the objects photographed, where they can be witnessed by an audience of any size. This fact was recently demonstrated to a party of physicians who were especially invited to witness the exhibition.

The value of this discovery cannot be overestimated, not only for the use of the scientist in studying the vital processes of microscopic life, but also as a method of teaching these facts to students and the public.

In my investigations, this method has been applied more especially to the study of blood-corpuscles. The active motion of the leucocyte can thus be readily reproduced. It can be seen to stretch out its finger-like prolongations and then retract them. The nucleus can likewise be seen to vary its shape, to split up into two or more, and sometimes the cell itself to divide into many parts.

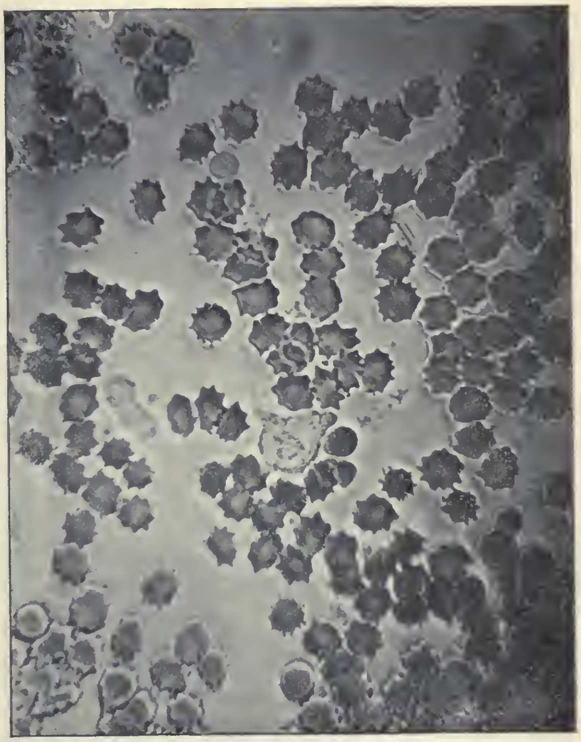
The accurate reproduction of these various vital processes of cell life will be of great assistance in revealing the exact condition of the blood, and help us to get one step nearer the ultimate processes of life. From what I have seen I do not hesitate to say that various cells now known by different names will be found to be only transition forms of the leucocyte. The ameboid motion of the leucocyte continues some times for fully twenty-four hours after the blood is placed on the slide of the microscope.

Another field of usefulness in which the micromotoscope will prove of service is in the study of the life of microbes in stale urine and other fermenting fluids. Indeed, it will be applicable to the study of the motile efforts of all microscopic germs and bacilli.

To secure an appearance of continuous motion these pictures must be taken in rapid succession, allowing an exposure of from $\frac{1}{50}$ to $\frac{1}{25}$ of a second; and to complete a full cycle of motion, as in the expansion and contraction of a leucocyte, requires from 800 to 1500 successive pictures.

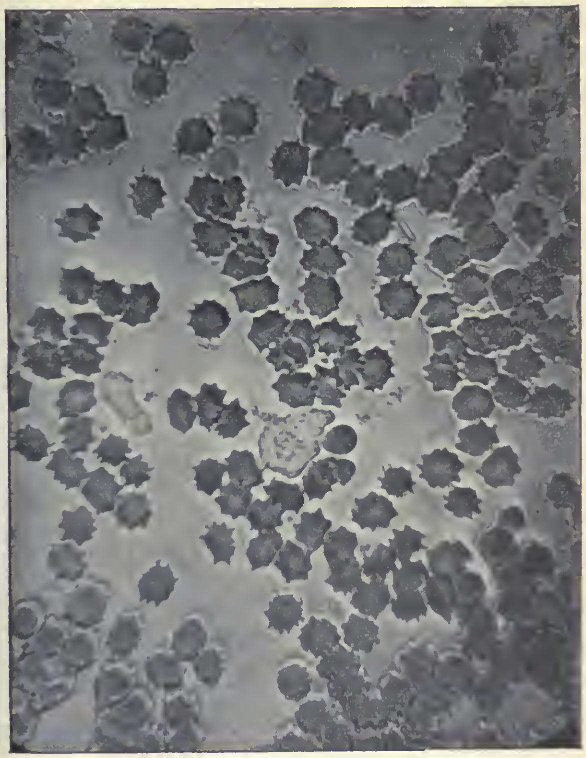
The accompanying photographs present, in a general way, an idea of the successive impressions as they appear in the vitascope.

FIG. 1.



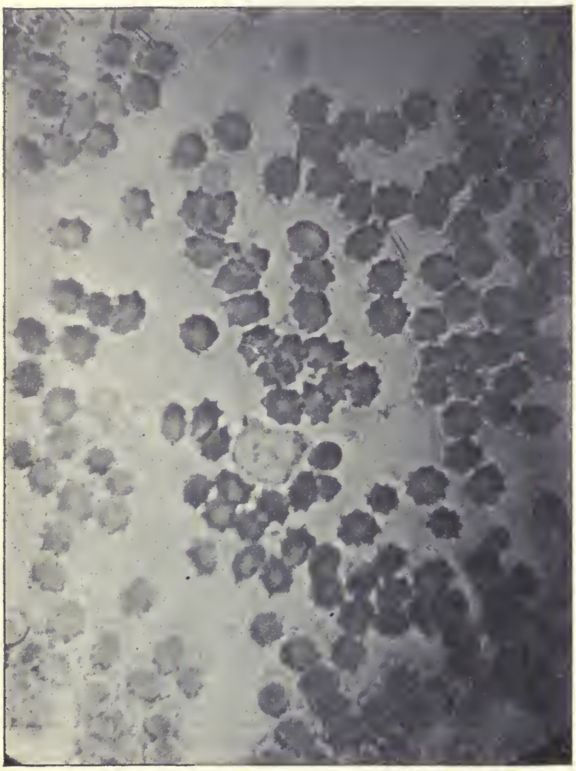
Freshly drawn blood, showing two leucocytes in center. Red cells mostly crenated. 1-12 obj., 2 ocul. Exposure, two seconds.

FIG. 2.



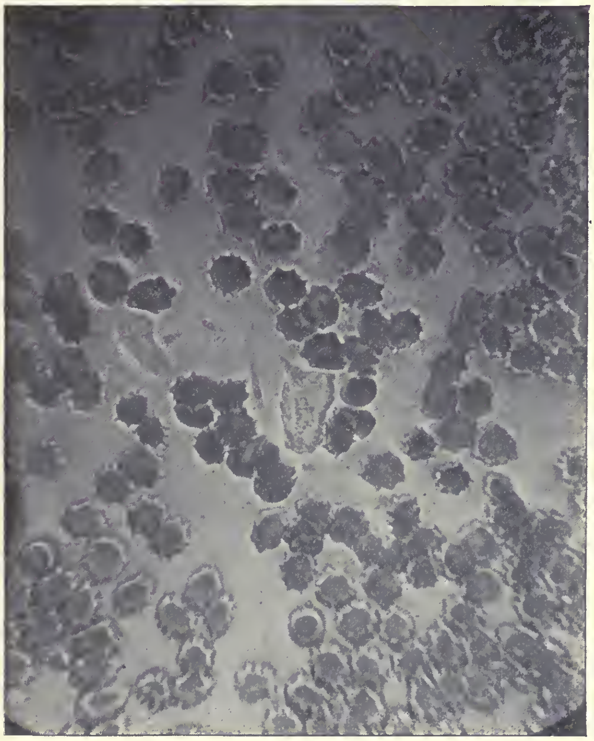
Taken two minutes after Fig. 1. Slight change in shape of large leucocyte. Nucleus also changed slightly in shape.

FIG. 3.



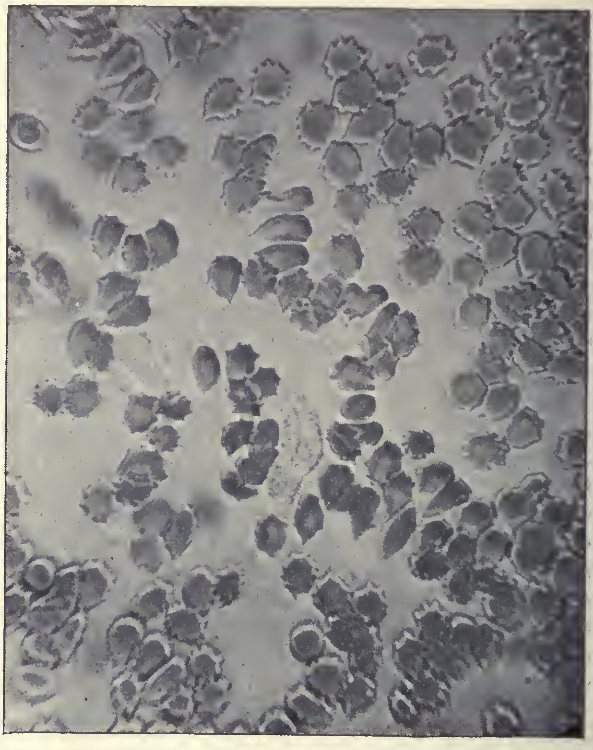
Fifteen minutes after Fig. 2. Leucocyte in center much changed.

FIG. 4.



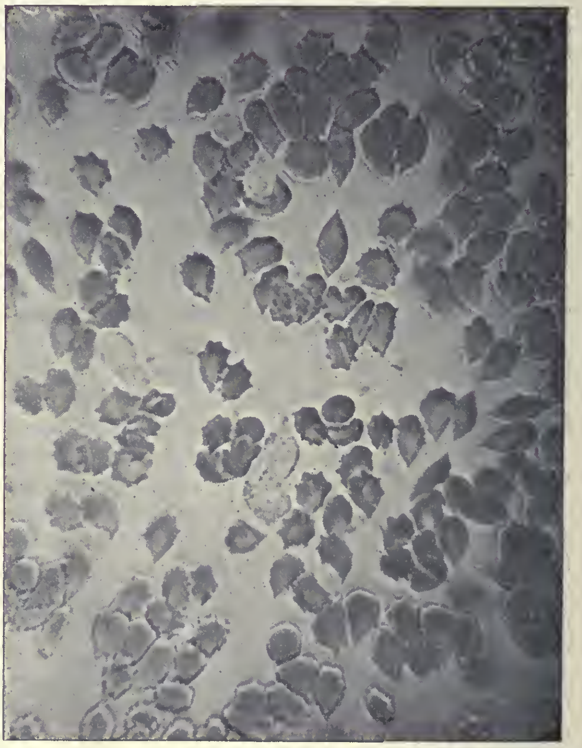
Finger-like prolongation very marked. Nucleus nearly gone. Contour still changing.

FIG. 5.



Elongation of same cell. Nucleus returning. Red cells in motion.

FIG. 6.



Finger prolongation distinct at top of large leucocyte, reaching out for a micrococcus. A division line seen below center of cell. Granules indistinct in various parts of the cell; probably micrococci being digested.

The time between the first and the second photographs is two minutes; the others are fifteen minutes apart, allowing an exposure of from one to two seconds.

The impression made by their rapid passage before the eye when placed in a vitascope gives, as is well understood, the sensation of continuous motion.

THERAPEUTIC NOTES.

For Sick Headache Due to Nervous Causes.—

℞	Atropin sulphate	gr. ss
	Chinoidin	ʒ i.

M. Ft. Pil. No. 9.
Sig. One pill two or three times daily.—*Bartholow.*

For Coexisting Pelvic Congestion, Anemia, and Constipation.—

℞	Magnesia sulphate		℥ i
	Iron sulphate Manganese sulphate	aa	℈ j
	Acid sulphuric dil.		ʒ ii
	Water		℥ iv.

M. Sig. A tablespoonful in a wineglassful of water before breakfast.

Treatment of Ozena.—MOURET (*La Med. Moderne*, May 8, 1897) found in the crusts from a nose affected with ozena: (1) Large streptococci in long chains and very abundant. (2) Diplococci with and without capsules. (3) Bacilli resembling those of Löffler.

Nasal irrigations, vibratory massage, cauterizations with chlorid of zinc, serotherapy, and electrolysis have all been successful in the hands of different men in the treatment of this disease, but the results have been only temporary. The author believes that the real cause of the disease is not yet known, but that the chief lesion is a trophic disturbance of the mucous membrane, vitiating profoundly the secretion of the glands. The temporary improvement noted after the various sorts of treatment is due to the expulsion of the crusts and the stimulation of the glands. This is best accomplished, however, by the use of vichy water or of bicarbonate of soda both internally and as a lotion, for the alkalies in general favor glandular action.

Massage in Recent Dislocations of the Shoulder.—MASSY (*La Semaine Med.*, May 19, 1897), in order to overcome the arthritis and periarthritis which result from the injury and attempts at reduction of a dislocated shoulder, makes use of massage in the following manner:

Two hours after the arm is in place and bandaged, or put in a sling, the shoulder is stroked lightly on all sides with the palm of the hand. This massage does not exceed five minutes in duration. In three or four hours it is repeated. The following day a somewhat stronger massage is given, consisting of stroking and kneading, and this is repeated after eight hours. On the second day a thorough massage is administered to the whole arm and shoulder-joint, consisting of the four motions of stroking, rubbing, kneading, and beating. This is repeated each day for fifteen minutes at a time, the arm being removed from its sling for the purpose and held by an assistant to prevent its dislocation. All bandages are removed at the end of a week, and the arm is carried in a sling for another week. By these means Massy obtains in uncomplicated dislocations complete cure in three or four weeks.

Rectal Treatment of Bronchiectasis in Children.—A treatment of bronchiectasis in children recommended by MOLLE is described in *La Semaine Medicale*, May 19th, as follows:

℞	Eucalyptol	2 parts
	Tr. of benzoin	10 "
	Balsam of copaiba	16 "
	Creosote	5 "
	Sweet almond oil	7 "

M.

This mixture is a clear and homogeneous liquid, of which thirty drops may be given in milk as an enema. The mode of administration is important. The child is placed on its side with its knees slightly drawn up, and a soft rubber catheter is passed four inches into the bowel. A small syringe is drawn nearly full of milk and then held in a vertical position while the half dram of medicine is poured into it. The air is expelled, and while the syringe is still held vertically the fluid is forced into the rectum. In this manner not a drop of the medicine is lost. The child experiences a temporary burning sensation to which it rapidly grows accustomed. If this treatment is persisted in for months, the expectoration, cough, and dyspnea all improve, the signs of dilatation, especially around the base, diminish, and the general condition is correspondingly better, even proceeding to a veritable cure.

Recovery After Cyanid of Potassium Poisoning.—WIGLESWORTH records in the *British Medical Journal* of April 24, 1897, a case of poisoning by cyanid of potassium, followed by recovery. A man aged twenty-five, in marked alcoholic intoxication, was seen to drink something from a bottle, throw the bottle away, and then fall. Almost immediately he passed into convulsions, and fifteen minutes later, when seen by the physician, he was unconscious, his face grayish-blue, and the jaws so tightly clamped that one of his teeth was broken in forcing open his mouth for the stomach tube. The eyes were fixed and the pupils dilated, but conjunctival reflex was not entirely absent. Breathing was pectoral and the inspirations jerky, resembling faint hiccoughs. The pulse was small and rapid. Through a tube the stomach was washed out with clean water and a mixture of sulphate of iron, carbonate of potash, and pure ether was passed into it. In about five minutes the patient vomited material which was stained a blue color. A stream of cold water was poured over the back of the neck and spine, and over the cardiac region. The pulse and breathing rapidly improved, but consciousness was not completely regained for four hours. From the fluid in the bottle it was estimated that if the patient drank two teaspoonfuls of it, he took not less than twenty grains of cyanid of potassium. He denied all recollection of having tried to poison himself.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

THE LIVER OF THE DOG THAT BIT YOU.

IT WAS recently shown by Koch that the bile of animals dying from the cattle plague possesses strong antitoxins; these he proceeded forthwith to use in the treatment of this disease. A writer in the *Münchener Med. Wochenschrift*, May 18, 1897, calls attention to the interesting fact that this method of treatment was recommended in the Talmud some thousands of years ago. Antitoxin treatment is there advocated also, not for the cattle plague, but for the bite of a mad dog, though of course the rabbi who spoke so highly of it knew nothing of its contained antitoxins. The quoted passage is to be found in connection with the laws for the feast of the passover, where, after a general statement that meat is allowed if necessary to save life, an instance is cited to the effect that when bitten by a mad dog a man should eat a portion of the animal's liver.

That there may be no mistake as to the necessity for this most unusual proceeding (for the dog was an unclean animal to a Jew), a very good description of hydrophobia is given. The animal is mad if with open mouth and streaming saliva and drooping ears and tail between his legs he runs from side to side of the street, barking hoarsely. It seems that the fight between the friends and the opponents of the antitoxin treatment waged even in the Talmud days, for other rabbis than the one quoted were not convinced of the virtue of this treatment; while the advocate of it asserts that the liver treatment must be instituted as quickly after the bite as possible in order to be of service.

It would seem that there must have been some good evidence of the value of such a remedy to cause a rabbi to recommend it in spite of the strong prejudices against "defilement." Whether it will be adopted as a practical remedy in our own time remains to be seen. Certain it is that it would be far more convenient to eat a piece of the liver "of the dog that bit you" than to travel to Paris to be injected at the Pasteur Institute; for the dog is of necessity near at hand, and Paris is, alas! far away. There would be, too, a sweetness of revenge in killing the dog and making him at the same time cure the trouble he caused.

PROSTITUTION AS A FACTOR IN PROGRESS.

I CAN conceive of no movement, capable of resulting in greater advantage to the community, in general, than the recent opening of THE MEDICAL NEWS for the frank, fearless, and intelligent discussion of the "Social Evil." I use these adjectives advisedly for the reason that although the question is as old as society itself, and the institution (if antiquity is to count for half as much here as it does in pedigrees and ritual) is entitled to the highest rank and consideration, the manner in which it is discussed is too often either insincere, cowardly, or irrational.

The subject is usually attacked either from the point of view of the self-constituted reformer (whose zeal and positiveness are exceedingly apt to be in direct proportion to his ignorance), or from the extreme legal or religious standpoint. The limitations of the legal mind, due to its idolatry of precedent in dealing with this question are too well known to need comment. As to the theologian, his attitude is most characteristic, generally at one extreme or the other according to his age, either deifying the sexual impulse, as in the unspeakable Phallic rites of antiquity (from which one of our now most sacred modern symbols, is more than suspected of being derived), or denouncing it as wholly sinful and degrading, at best a concession to poor weak human nature which may be tolerated because it cannot be suppressed. Between the Pauline attitude and the Black Plague of monasticism on the one hand, and the Phallic worship with its bacchanalian rites on the other, there is but little to choose, either as to rationality or actual moral results. And yet one or the other of these conceptions has usually dominated most ecclesiastical contributions to the solution of this question. Celibacy or virginity is still the ideal condition of the saint.

Without any wish to disparage others, it is my firm belief that the only class of men in the community who know the facts of the situation personally, and thoroughly appreciate the impulses and appetites which underlie them, are the members of our own profession. These underlying facts, however, have never been systematically collected, nor have many of us as yet thoroughly thought out the question to its ultimate terms. Hence, the extreme value of such a discussion as this which can hardly fail to produce results of permanence and far-reaching importance. Especially as the discussion can be perfectly frank and outspoken, which the secular press of any class dares not be, for fear of the awful shade of Mrs. Grundy, or the hysterics of the W. C. T. U. In "seconding the motion" for this professional experience-meeting, I beg to submit for approval or disapproval, a few suggestions as to the racial economics of prostitution, which usually, to my mind, are hardly given their proper weight. And perhaps I may be permitted to say, in introduction, that these tentative conclusions are based upon an investigation of the question, begun some years ago, in which after an exhaustive (and exhausting) discovery of the "plentiful lack" of either reliable statistics, or competent, unbiased opinions in the literature of the subject, the chief reliance was placed upon the responses to a large number of letters, addressed to the leading members of the profession in all the chief cities of the Union.

The vital questions of the problem are two in number; first, what class and character of men and women are affected by this institution? and, secondly, in what way are they affected? First, as to the women: The almost unanimous testimony of the replies received, as well as of the figures of Du Chatelet in Paris, is (*a*) that ninety per cent. of prostitutes are drawn from the lowest and most ignorant class of the population; (*b*) that they are led to this life by the desire for luxury, display, and idleness, a purely trade-instinct in fact, and *not* by strong sexual impulses, want, or seduction and desertion; (*c*) that their average life-time after entering this career is 9.5 years; (*d*) that during this period they are practically sterile; (*e*) that very few of them permanently reform, and those who do are extremely infertile. Now as to the men. Unlike the women they are drawn from no single class, condition, or age in the community, but from all alike. They are drawn into the vortex by an instinct it is true, but not a *natural* one—a *perverted* one. It is astonishing how little "passion" there is in the trade on either side. So far from the "hot blood of youth" being chiefly responsible, houses of ill-fame derive two-thirds of their income from married men over forty. In fact the essential "*Leit-motif*" of the practice is not the sexual impulse pure and simple, but the desire to indulge that impulse *and escape* its natural and legitimate consequence, conception. And in this respect women are just as much to blame as men. Many a man is driven to the brothel by his own wife. Three sources chiefly feed the reeking stream of prostitution, two of which are best characterized in the phrases, "can't afford to marry," and "don't want to be bothered with children," and the last and chiefest is limiting unduly the size of families. This is the civilized successor of infanticide, and like it, is the racial "sin against the Holy Ghost, which shall not be forgiven."

How are the supporters of this "institution" affected by it? The general impression is, especially in respect to the women, that they are rapidly killed by venereal disease and sexual excess, but upon gathering reliable facts we find the actual mortality from either of these causes decidedly low. Brain-syphilis and locomotor ataxia among the men, and gonorrheal peritonitis among the women, are almost the only actually fatal forms of venereal disease, and when we come to examine the "bogey" of "sexual excess" we are simply astonished to find how few permanently injurious results of any sort are produced by it. What, then, does shorten the life of the prostitute? My replies were absolutely unanimous upon this point and surprised me greatly. *Every* observer gives *alcohol* the first place, morphin, chloral, and venereal disease come almost together as bad seconds, suicide is fourth, and irregular hours and exposure next. Thus alcohol is found here, as elsewhere, one of the best friends of civilization. It is worth all the police systems and "missions" ever invented for the elimination of the criminal.

But although this vice has so comparatively little direct effect upon the life chances of its patrons, it affects them all with great force and certainty in another respect. It is a most efficient sterilizer. The prostitute, of course, for obvious reasons, seldom bears children during her "active" life, and usually becomes sterile sooner or later by endometritis or salpingitis, before alcohol or premature old age claim her. She seldom "reforms" (thank Heaven), and if she does, bears few children.

Now as to the man. Supposing he is infected with syphilis, what results? Under any circumstances or any treatment he is absolutely sterile for from two to seven years, either by abstinence or by the infection of whatever woman may be unfortunate enough to be his wife, during that time. Abortion after abortion occurs until viable children are born, but even then ——— ! Tarnier declares that eighty-five per cent. of syphilitic children die before the sixth month, Sturgis seventy-one per cent. As to gonorrhea, the revolution in professional opinion in this regard is simply startling. No longer regarded as a mere trifle, its effects are found to be appallingly widespread. Orchitis on the one hand and pyosalpinx on the other spring up in swarms in its wake like veritable dragon's brood. The despairing cry goes up, "It is doubtful whether gonorrhea is ever cured!" Here, again, justice may move with a leaden foot, but she strikes with an iron hand." That insignificant little infection gonorrhea, "of no more importance than a cold in the head," is found to be followed by a Nemesis of infirmity which is simply appalling.

To sum up then, from the female side of this institution, our conclusion would be that it is concerned principally with the most worthless variety of women, the degenerates or criminals, and the idle, the mercenary, and shameless of the working classes: in short, women whom the community can well afford to spare. That these women, when fairly in its grasp, are practically prevented from propagating their kind during their career, and rapidly destroyed if they remain in it. That very few marry, and those who do so are barren in a high degree; in short, it is an eliminative agency of high value and wonderful efficiency for first rendering sterile and then rapidly destroying the worst specimens of the sex—women whose "reform" and child-bearing would be a curse to the community. No need to spay the prostitute or castrate the criminal: they'll do it themselves if they are just given a little time.

To say that prostitution involves fearful and widespread suffering to innocent women and children would be as true as it is pitiable and harrowing, but "a companion of fools shall be destroyed" is no vengeful threat, but a simple statement of a stern necessary law, of highest value to the race. The only way to check its ravages is to reduce to the lowest possible limit the class upon which it is sure (and ought) to act. And the only agency of any value in this work is education, *education*, EDUCATION! Legislation is useless, "regulation" worse still. Awake society to the fact that the rake does *not* make the best husband, especially awake the "managing mammas," who are for the most part either shamefully ignorant and determined to keep their charges so, or as conscienceless, in these matters, as the slave-dealers of the Soudan.

Above and beyond all we should foster, glorify, deify if necessary, the one instinct in man's bosom which can master the sexual, the highest, the holiest, the strongest of which he is capable,—his love for the one woman who is, or is to be, all the world to him. Once touch this spring and he is safe. Well may all of clearest and deepest vision among us, the poets, never weary of singing its praises. The age of chivalry should be brought back in nobler, truer form. Lust laughs at opposition and exults in danger, but sinks ashamed at the whisper of love. Impress upon every man not his own danger, but that of his wife that is to be, of his children yet unborn. Nay, further, make him to see that the last insult he can offer to the one for whom he would cheerfully lay down his life, is to make, in the burning words of the apostle, her "members the members of a harlot." Do this, and prostitution will disappear from the face of the earth.

WOODS HUTCHINSON, M.D.

ECHOES AND NEWS.

Lord Lister and Professor Max Muller Honored.—Lord Lister and Professor Max Müller have been elected members of the Imperial Academy of Sciences of Vienna.

Diphtheria Antitoxin in Chicago.—The statistics of the Department of Health of Chicago credit diphtheria antitoxin with the saving of no less than 750 lives in that city during the year 1896.

Locusts as a Source of Poisoning.—Several cases of poisoning are reported from various towns in Pennsylvania, the result of eating the eggs and flesh of fowls which had been feeding on seventeen-year locusts.

The Death of Dr. Purshotum Dawda.—Dr. Purshotum Dawda, in charge of the Lohana Plague Hospital, was attacked with plague and died on the 1st instant. He is the fourth medical man who has died of the malady at Bombay.

Famine and Plague in China.—Recent advices from China say that the fatality from famine and plague in that country is appalling. The nature of the plague is not reported. Smallpox is prevalent in Tokio, Japan; also, in the island of Formosa.

The Potent Effects of the Word Hypnotism.—It is reported from New Haven, Conn., that a spiritualistic medium, when told that an expert hypnotist would be present at the next meeting of her society, went into a cataleptic condition, from which she had not recovered at the expiration of three days.

Two New Professorships at Columbia University.—At a meeting of the trustees of Columbia University, held June 8th, two new professors were appointed in the medical department—College of Physicians and Surgeons—namely, Dr. Jas. Ewen, Professor of Clinical Microscopy, and Dr. A. Brayton Ball, Professor of Clinical Medicine.

The Jubilee Number of the "Practitioner."—The *Practitioner* for June appears as a handsomely illustrated jubilee number, in commemoration of Queen Victoria's diamond jubilee, the whole number being devoted to an account of the advances made in medicine, surgery, and the allied sciences during the sixty years of her reign.

Johns Hopkins University Bestows the Degree of M.D. for the First Time.—Commencement exercises at Johns Hopkins University on June 15th were rendered unusually interesting by reason of the fact that for the first time in the history of the institution the degree of M.D. was conferred upon its graduates, fifteen in all. One of the graduates was a woman.

Imprisonment for Expectoration in Street Cars.—News comes from San Francisco, Cal., that W. B. Bradbury, the millionaire, will have to serve the sentence of twenty-four hours' imprisonment in the county jail imposed upon him on his conviction for the second time of expectorating in street cars. This decision has been confirmed by Judge Wallace of the Superior Court.

The Superintendent of a State Insane Asylum Removed.—Dr. George Allen, who was recently appointed superintendent of the Collins' State Homeopathic Hospital, Erie County, N. Y., has been removed by the Board of Managers. Dr. Allen was appointed to the position from the asylum at Middletown. The removal is the result of trouble over a question of appointment.

The Discovery of the Yellow-Fever Germ.—The announcement by Dr. San Arelli that he has found the true germ of the disease has awakened new interest in the bacteriologic origin of that disease. Physicians and scientists from Europe, as well as various parts of South America, are assembling at Montevidio, Uruguay, for the purpose of studying the life history of the germ and discovering an efficient germicide.

The New Harlem Hospital.—The site for the new Harlem Hospital of New York City, to be erected at a cost of $300,000, has been chosen by the Commissioners of Charities. The location selected is the block fronting on the east side of Lenox Avenue, between 135th and 136th Streets, and having a depth of 400 feet. Steps are being taken for the purchase of the property under condemnation proceedings.

The Membership of the Congress of American Physicians and Surgeons.—In our editorial of last week this Congress was described as "a body of some 600 men." This evidently placed the number at altogether too low a figure. The secretary of the Congress, Dr. W. H. Carmault, writes that there are 1157 active members, 41 corresponding members, and 109 honorary members, making a total membership of 1307.

The Generosity of Madame Charcot.—Madame Charcot, the widow of the late Professor Charcot, has relinquished the annual pension of 2000 francs (over $400) which she received from the State in favor of other widows and children of professors or *Agrégés* of the Faculty of Medicine of Paris who have died without leaving provision for their survivors. Madame Charcot has refunded all the money which she has received from the pension since the death of her husband.

A Dinner to Dr. H. A. Didama.—The faculty and the Alumni Association of the College of Medicine of Syracuse University gave an elaborate dinner on June 9th last in honor of Dean Henry D. Didama, M.D., LL.D., on the occasion of his fiftieth anniversary as a practitioner of medicine. After the menu had been satisfactorily discussed, a series of interesting after-dinner speeches were indulged in under the supervision of the toast-master, Dr. Nathan Jacobson of Syracuse.

The Roentgen-Ray Diagnosticates a Broken Neck.—It is reported from Camden, N. J., that a boy nine years old fell from a tree recently with serious consequences. Upon striking the ground, the boy lay limp and unconscious, with blood running from his mouth. Later, paralysis of the lower limbs developed. A diagnosis of dislocation of the spine was made. This was confirmed by the Röntgen-ray, which showed the spine dislocated in three places. The boy has continued to live for a week since the accident.

Yellow Fever at New York Quarantine.—One death has occurred among the second-class passengers detained in quarantine at New York. After proper detention and thorough disinfection, the remainder of the passengers have been dismissed. The Health Officer, Dr. Doty, regards five days as the safe limit during which passengers subject to infection should be kept under observation. Dr. Doty says: "Epidemics of yellow fever have been prevalent during the last two and a half years in Rio Janeiro, Santos, and Cuba, and in spite of the constant arrival here of ships from these ports, not a single case of yellow fever has entered New York."

A Bill to Provide Expert Witnesses.—It is said that a bill has been introduced in the Minnesota Legislature providing for the appointment of expert witnesses, and that the homeopathic physicians have, with legal advice, prepared a bill to be presented in the New York Legislature. The object of the bill is to provide a list of experts from whom witnesses are to be selected by the Court and paid by the State. The employment of expert witnesses by the counsel of the prosecution or defense has been unfortunate both for the courts and for science. It would certainly be desirable to devise a plan by which the expert witness should be in the position of a judge rather than that of a paid attorney.

New Measures of the New York Board of Health to Guard Against Hydrophobia.—The New York Board of Health has arranged to investigate every case of supposed rabies reported in the city. All policemen are instructed to report every case to the Board of Health. The Health Department ambulances will then take the animal to their laboratory for examination. Cultures will be made and injected into rabbits, guinea pigs, and other animals. This will definitely determine whether hydrophobia is to be feared as the result of any individual dog's bite. People see a dog frothing at the mouth and at once rush to the conclusion that it is mad, forgetting that a dog perspires at the mouth, and that its frothing at the mouth may simply mean that it is hot or excited, or the dog may have fits.

New York Newsboys Not Physical Prodigies.—Forty boys from a newsboys' home in New York City were marched over to the Navy Yard recently to be examined for admission to the navy. They ranged in age from fifteen to eighteen years, with records for physical prowess, the superintendent of the home said, that would entitle them to prominent positions in any fighting detachment. The boys were all jubilant at the prospect of becoming sailors. They were put through the severe physical examination to which applicants are subjected, and with surprising results. Out of the forty applicants thirty-eight were rejected on account of physical defects. The cause of rejection of most of the candidates was the unsoundness of their teeth. One boy's skull was discovered to have been cracked and mended at some period of his life. He was rejected.

The Death of Dr. George F. Edwards.—A most pathetic incident of the commencement exercises at Princeton University last week was the presence there and the death of Dr. George F. Edwards. Dr. Edwards during his college days was a famous character, hail-fellow-well-met with the members of all the classes, possessed of a fund of good nature, witty, loyal, and generous. He was no class man in a strict sense, but belonged to all classes. He was received with open arms at all the *fêtes*. He graduated in the class of '89. Subsequently he entered the medical department of the University of Pennsylvania, where he was graduated with honors. After a brief service in the Presbyterian Hospital in Philadelphia, he went to Johns Hopkins University and began the study of tuberculosis. While there he was infected with the dread disease, the first signs of the malady appearing in him about three years ago. Then began the fight for life. He went to the Pacific slope in quest of health, but the disease had too tenacious a hold upon him, and he realized he had not much longer to live. The pleasantest experiences of his life had been at Princeton College, and his desire was to see once more the scenes of those good times, to spend a few hours in old East College where he had roomed, to witness a struggle on the baseball field with Yale, to attend another Ivy dinner, and then pass away. All these desires were realized, and then the end came in the old room in which he had spent happy years. His final will was made there by which he left a handsome sum to a negro boy, whom he had befriended and educated, and the balance of his fortune, amounting to $150,000, to Princeton University.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

SUMMER WORK IN THE CLINICS—A SCHEME TO AID "BACKWARD STUDENTS" IN PASSING THE STATE BOARD OF MEDICAL EXAMINERS—SECTION ON GENERAL MEDICINE, COLLEGE OF PHYSICIANS OF PHILADELPHIA—A FOUR-YEARS' COURSE AT THE MEDICO-CHIRURGICAL COLLEGE—THE PHILADELPHIA HOSPITAL EXAMINATIONS.

PHILADELPHIA, June 19, 1897.

WITH the closing of the various medical schools and the final meetings, until the fall, of the more important medical societies, it would seem to the casual visitor that the medical world of Philadelphia has settled into a three-months' summer desuetude; but, although surface indications may point to a state of *laissez aller* when contrasted with the work of the great clinics during the winter months, one has only to drop into any of the large hospitals on clinic days to obtain evidence of the fact that, though many of the leaders have exchanged stethoscope and scalpel for rod and oar, much valuable and earnest work is being carried on during these hot months by the younger men of the profession, and in a manner which ensures not a few of them a future high place in their calling.

In many ways these summer clinics offer to the student advantages which it is obviously impossible to present during the crowded winter terms. Brilliant didactic lectures, and equally brilliant clinical teaching is not to be found, it is true, but, on the other hand, the summer student may freely avail himself of such advantages as close personal contact with both patient and teacher, and an intimate acquaintanceship with the ins and outs of the operating-room and the routine at the bedside, and learn for himself many points which would be missed or unappreciated by a listener on the benches. That this individual instruction is valued by the knowing student of medicine is shown by the good attendance at the regular summer courses of the medical schools, and at the clinics and operations at the various hospitals.

Covert cheating in examinations, whether in a preparatory school, university, or technical school, has always existed to a more or less degree, and will doubtless always continue to exist, except in those institutions in which the students have voluntarily pledged themselves to discountenance "cribbing." Unfortunately, the medical student body is no stranger to this evil, as the facts attest in the wholesale attempts at cheating in the examinations now being held in this city by the State Examining Board for licenses to practise medicine in Pennsylvania. It would seem that an enterprising but unscrupulous ex-student of medicine contracted to furnish those candidates whose mental capacity and standard of honesty happened to fall a bit below the standard with complete "ponies" for the ordeal, at the rate of three dollars for a set covering all the branches of medicine. These "aids to backward students" consisted of small double rolls of paper, on which were printed in very fine type quite an accurate compendium of the different branches, and of a size which permitted their manipulation while held in the palm of the hand.

Many of these "ponies." were sold during the weeks preceding the examination, but the traffic finally became so open and so extensive that, thanks to the efforts of a daily newspaper whose reporter himself purchased one of the incriminating paper rolls, the Examining Board became aware of the matter, and took prompt measures to circumvent the scheme. The result of their vigilance was that a number of candidates were detected using the "ponies" and were unconditionally expelled from the examinations. It is said that there were found on the floor of the examination-room, at the close of the examinations, quite a collection of fragments of "cribs" and other bits of paper indicating that the number of guilty candidates was not small.

The last stated meeting until September next of the Section on General Medicine of the College of Physicians of Philadelphia was held on June 14th. Dr. H. A. Hare made a few remarks on "The Value of the Various Preparations of Digitalis," during the course of which it was explained that of the substances isolated from this drug, digitalin, digitalein, and digitoxin exerted a decidedly tonic influence on the heart, and also at times might be capable of producing spasm of the renal vessels; while digitonin acted as a cardiac, depressant, and renal stimulant. He thought that some of the conflicting reports as to the action of digitalis could be explained by the different preparations used, and by the varying physiologic actions of the same preparations made by the various manufacturers.

Dr. J. C. Wilson read "A Brief Statistical Paper on Enteric Fever in Children, based upon 150 Hospital Cases." This paper comprised fifty cases of enteric fever treated at the Mary J. Drexel Home connected with the German Hospital and one hundred cases from the records of the Pennsylvania Hospital during the last twenty-five years. After logically deducing the important facts connected with enteric fever in childhood, Dr. Wilson showed that the mortality in children under fifteen years of age averaged four per cent., and that in young children the fever was less marked, the duration of the disease was shorter, and that relapses were rare.

Dr. C. W. Burr reported an interesting case of osteomalacia.

It is announced by the Board of Trustees of the Medico-Chirurgical College that, beginning with the coming session of 1897-98, the college course will be lengthened to four years. By the action of this institution all the medical schools of this city now require a compulsory four-years' course for the doctorate, this requirement having already been inaugurated by the Medical Department of the University of Pennsylvania, the Jefferson Medical College, and the Woman's Medical College.

Food for reflection may be found in the results of the examinations recently held for the positions of resident physicians in the Philadelphia Hospital. Of the ninety-five applicants examined, but twenty-one attained the average of seventy per cent. necessary to place them on the eligible list. Some seek to explain the results by the rigidity of the examination, some attribute it to the mental caliber of the applicants, while others place the blame on an indefinite combination of circumstances such as have been known to carry failure to the best of students. But the questions this year were not particularly difficult, the average graduate of this year's classes is certainly as bright as his classmate of a year ago, and the latter reason is too intangible for consideration. The fact, therefore, remains unexplained that only about twenty-two per cent. of the applicants reached a grade of seventy.

ANNOUNCEMENT.

TWELFTH INTERNATIONAL CONGRESS OF MEDICINE.

TO BE HELD UNDER THE HIGH PROTECTION OF HIS MAJESTY, NICHOLAS II., AND THE AUGUST PATRONAGE OF HIS IMPERIAL HIGHNESS, GRAND DUKE SERGE ALEXANDROVITCH, AT MOSCOW, AUGUST 19–26, 1897.

THE Committee of Organization of the Congress has received from the Minister of Transportation nearly 7000 free first-class tickets, which it holds at the disposal of the members of the Congress for their journey to and from Moscow.

These tickets have been offered to the Committee of

Organization by the minister under the following conditions:

1. The Committee of Organization, in sending each ticket to the member of the Congress for whom it is intended, will write upon it his family name, the place from which he will take his departure, and, if the member is a foreigner, the first station on the Russian frontier; also, the route he will follow to reach Moscow and to return.

2. Aside from this, the Committee of Organization will furnish members of the Congress with a certificate indicating that the bearer has paid his assessment and is really a member of the Congress. These certificates shall, on demand of the conductor of a train, be presented to him by the bearers thereof.

3. No ticket will be good for the return trip from Moscow unless it has been furnished by the Committee of Organization with a stamp indicating that "the bearer has attended the International Congress."

4. The names of the members of the Congress may be written, according to the decision of the Committee of Organization, not only in Russian but also in a foreign language.

5. The tickets to Moscow should be presented at the ticket office of the place of departure, or at the first station on the Russian frontier, in order that the stamp of the train may be affixed. On the return trip these tickets are to be presented at the Moscow railway station, where the stamp of the day of departure (old style) will be affixed.

6. The tickets will be good from the 1st to the 13th of September of the present year.

7. Every bearer of a ticket will be allowed to carry free sixteen kilograms of baggage.

8. As soon as the Committee of Organization shall have given notice of the time of arrival at the frontier station of the members of the Congress and their number, the Board of Directors of Railways will make arrangements to permit them to reach Moscow as comfortably and speedily as possible. The same arrangements will be made on their departure from that city.

In accordance with these conditions, in order to have a free ticket, each member of the Congress should inform the Secretary-General of the route which he will follow to and from Moscow.

The Executive Committee has the honor to add that ladies and other persons not having scientific titles, who accompany members of the Congress (Section 3, Rules of the Congress), cannot be designated as being in attendance. They pay no admission fee and do not receive free tickets on the lines of the Russian railways.

Death of Professor Charteris of Glasgow.—Professor Charteris, of the Chair of Materia Medica in Glasgow University, died on June 7th. He was living at Comrie, in Perthshire, having obtained leave for the summer session, in order to recuperate after an attack of influenza. His illness took a decidedly serious change on Sunday, and he died on the following day, soon after the arriva of one of his colleagues.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

The Semicentennial Meeting, Held at Philadelphia, June 1, 2, 3, and 4, 1897.

SECTION ON PRACTICE OF MEDICINE.

(Concluded from page 848.)

FOURTH DAY—JUNE 4TH.

The following resolution was unanimously adopted;

"*Resolved*, That Professor Welch and others who took part in the discussion on sero-diagnosis be appointed a committee to draw up a brief statement of the consensus of opinion arrived at through this discussion, this statement to be published in the *Journal* of the Association in connection with the report of the discussion."

Pursuant to the provisions of this resolution the following committee was appointed: Drs. Welch of Baltimore (chairman), Wyatt Johnston of Montreal, R. C. Cabot of Boston, W. H. Bloch of Baltimore, H. M. Biggs of New York, S. S. Kneass, J. H. Musser and John M. Swan of Philadelphia, Mark W. Richardson of Boston, N. S. Davis, Jr., of Chicago, and A. P. Ohlmacher of Cleveland.

The regular session was opened by a discussion on GOUT, inaugurated by DR. WOODS HUTCHINSON of Buffalo. He said that gout is one of the most protean of diseases in its manifestations, a perfect Pandora's box from which every variety of ailment might escape to attack every organ in the body. As manifestations of the lithemic diathesis, and thereby closely allied in their causation to gout, might be mentioned dyspepsia, which is largely of lithemic origin, neuralgia, and hay fever, often due to the presence of uric acid, while two-thirds of the cases of rheumatism can be traced to the same cause as gout. Many inflammations of the bladder have a similar origin, while laryngitis and pharyngitis are also manifestations. Bright's disease is due to the same cause, and the weakening of the arterial coats in this malady is the work of uric acid. The uric-acid diathesis is very closely allied to the vital processes, and though the term is inexact, it is better to stick to a term that is known to be wrong rather than to search around for another that will be no nearer right.

Lithemia is quite common in some animals, while it is rare in others. Those in whom hippuric acid is formed are not subject to lithemia, and among these might be mentioned parrots and domestic fowls. On the contrary, those animals that form uric acid are subject to the lithemic diathesis. Urea is a comparatively harmless substance, while uric acid is very poisonous, and therefore the deposits of bony material in a gouty joint may be regarded as a decidedly conservative process. The inflammation in the joint stimulates the formation of fibrous tissue, and this process is analogous to the building of coral reefs by the coral insect, and to the throwing out of calcareous matter for the formation of a shell by mollusks. It is a defensive process. When there is an abundance of lithemic cells in the system there are fibrous deposits. There is an antagonism between the uric-acid diathesis and tuberculosis.

In the matter of treatment, the essential thing is to keep the patient up to a proper condition, and the way to accomplish this is by exercise, exercise, and more exercise. If a man would observe the direction given by Abernethy to "live on a shilling a day, and earn it," he would never suffer from gout.

Dr. Charles Stockton of Buffalo spoke of the "Gastro-intestinal and Hepatic Relations and Manifestations of Gout." He said that he and Dr. Hutchinson agreed in many particulars, but differed in others. After listening to Dr. Hutchinson he was always inclined to doubt his own experience, but in the present instance he hoped to break down at least one of his contentions. Discussing the causation of gout, the question arises as to whether lithemia is gout, or whether the disease is the result of a toxemia due to disorders of the digestive functions, including the liver. The fact that relief of the gouty symptoms does not follow a treatment directed to the gout itself, but that they disappear upon regulation of the diet, points to the latter hypothesis as the correct one. The fact that outbreaks of gout follow indiscretions of diet in gouty patients is also suggestive. The regulation of the diet should be based upon a study of each individual case, for some persons do well on albuminous diet and badly upon a nitrogenous one, while others improve upon a nitrogenous diet but get worse upon an albuminous one.

Dr. Charles A. Oliver of Philadelphia next discussed "Gout as it is Manifested in the Special Senses," confining himself entirely to its effects upon the eye. The symptoms of gout, as seen in the eye, are those of swollen and angry-looking lids, and inflammation of the conjunctiva, but without ulceration. As Dr. Hutchinson had said, the treatment for the general manifestations of gout is exercise, exercise, and more exercise, and the treatment for its manifestations in the eye should be the application of heat, heat, and more heat. Desquamation of the corneal epithelium is frequently noted, and infarctions in the Meibomian glands are not uncommon. The inflammation set up in the eye by the gouty diathesis may be carried back into the ciliary body. The vessels in the back part of the eye may become very much enlarged, and almost macroscopic in size. Entire blindness never results, but there may be central blindness. Inflammation not only exists in the orbit, but may extend back into the optic chiasm itself.

"The Relations of the Alloxur Bodies to Gout, or a Uric-Acid Diathesis, with Demonstration," was discussed by **Dr. T. B. Fletcher** of Baltimore.

Dr. F. S. Pearce of Philadelphia discussed the question of "The Relation of Uric Acid to Neurasthenia," and came to the following conclusions: (1) That the amount of uric acid present in cases of neurasthenia is less than normal, and that disturbed metabolism is the cause of many of the symptoms; (2) that interference with the exudation of the products of uric acid is the cause of many of the secondary symptoms; (3) that an increase of uric acid may cause an exacerbation of the symptoms; (4) that neurasthenia is not always due to uric acid but to a perverted metabolism and to idiosyncrasy; (5) that uric acid must exert a considerable influence on neurasthenia; (6) that back of all these exciting causes is the predisposing cause of excitable neurons; (7) some of the severe headaches in neurasthenics may be due to the infection of the meninges; the presence of uric acid may also explain the severe occipital pain experienced by some neurasthenics which eye treatment has failed to relieve; (8) that in the treatment of uric-acidemia the use of alkalin mineral waters and of baths is useful.

Dr. H. C. Wood of Philadelphia spoke on "The Treatment of Gout." He was expected, he said, in the course of fifteen minutes to epitomize the wisdom of ages. All the scientific knowledge of gout at the present time amounts to little more than a mass of "mumbling explanations," upon which should be built up a true knowledge of the disease. There are three great manifestations of lithemia — articular rheumatism, rheumatoid arthritis, and podagra, or true gout. He traced the genealogy of a case of gout through four generations, beginning with the great-grandfather, who acquired true podagra in England—a form practically unknown in this country, which passed through four generations, manifesting itself in various ways, until it culminated in the great-grandson in attack after attack of acute rheumatism. It was not the same disease in each person, but it was the same element which had been eluding the grasp of the profession for a hundred years. Until the profession purges itself of the false knowledge of gout which it thinks it possesses, and recognizes the great principle that it is not the gout which should be treated, but the individual with gout, no advance will be made in the treatment and cure of this condition.

Exercise is better than drugs. Colchicum will do good in cases of typical gout, but these do not occur in this country. In order to get results from these drugs it is necessary to give "knock-down doses" of the salicylate of colchicum. In the administration of salicylic acid the profession has long been accustomed to give it in the form of salicylate of sodium, which is not so objectionable as the salicylic acid and soda given separately; but he has had better results from the use of the salicylate of ammonium and salicylate of strontium, giving the ammonium salt in acute cases and the strontium salt in subacute cases. Sometimes he combines them. Baths have been recommended, but he does not see how they can accomplish anything, as "it would be necessary to take a Turkish bath every hour in order to wash away the ancestral vice" in cases in which the disease has endured for several generations.

"The Cardio-vascular and Renal Relations and Manifestations of Gout" were discussed by **Dr. N. S. Davis, Jr.**, of Chicago.

Dr. James Tyson of Philadelphia said that gout is a disease to which he has given much thought and in the treatment of which he has had much experience. No disease is so carelessly diagnosed as gout, and one of the symptoms on which a diagnosis of gout is most frequently based is the appearance of Heberton's nodosities, which, in reality, are not a symptom of gout at all but occur more frequently in rheumatoid arthritis. He agreed with Dr. Stockton that uric acid in the urine is not always a symptom of gout, but when a man is known to have a gouty diathesis it is safe to call all unusual symptoms manifestations of gout. For the treatment of gout he advocates the use of alkalin mineral waters between the attacks. Gout cannot be cured, but its manifestations may cease, and the constant effort of the physician and patient should be directed to keeping them in abeyance. The best waters for this purpose are the foreign Vichy and Baden waters, for there are no true mineral waters in this country. Of course the diet should be attended to. In the medicinal treatment of gout he has obtained the best results from the use of salicylate of soda, but recently he has gone back to the old custom of giving salicylic acid and carbonate of soda. Sometimes he uses the salicylate of strontium.

A paper was read by Dr. David Riesman of Philadelphia upon

RHEUMATOID ARTHRITIS.

He prefers the term "osteo-deformans," as recommended by Virchow, and regrets the fact that the profession does not know as much about the pathology of rheumatism as it does of diphtheria and other diseases. Next to the pain in the joints, the most striking feature in rheumatoid arthritis is the atrophy of the muscles connected with the affected joint. He divided the disease into (1) Osteo-deformans of the severe type; (2) osteo-deformans of a mild type; and (3) localized deformans. Heberton's nodes are more common in women than in men, and frequently begin to develop at the menopause. He has also known Heberton's nodes to develop shortly after an attack of diphtheria. Three explanations have been given for the condition: (1) That it is due to a complication of rheumatism and gout; (2) that it is of nervous origin; (3) that it results from a specific germ. The treatment should be directed toward preventing contracture of the affected joints by the application of an extension apparatus. He was convinced that some of his cases would have become helpless cripples but for this extension. The medicinal treatment consists in the exhibition of strontium bromid, which, he believes, possesses the power of limiting the disease.

A discussion on Anemia followed, opened by a paper by Dr. Alfred Stengel of Philadelphia, which was read by Dr. A. E. Taylor of Philadelphia. Anemia is dependent upon something more than a diminution in the quantity of the blood; an alteration in the blood plasma, and in the number and distribution of the corpuscles will be found to exist. This is shown by the experiment of bleeding a dog of one-third of his volume of blood, and examining the remainder at intervals. It will be found that there is a dilution of the remaining blood plasma, and that the specific gravity drops several points. Alterations in the number of red blood-corpuscles is not now considered the important factor it was once held to be. Distribution of the corpuscles in the plasma is of more importance. Anemia is considered to be a deterioration of the blood, with an alteration in its solid constituents. The classification of anemia is difficult, the usual division being into primary and secondary. Pernicious anemia is a secondary disease, and is not considered to be due to any disorder of the hemopoietic system, but is a consequence of syphilis, rickets, chlorosis, and the like. It can be distinguished by the examination of the blood alone, notwithstanding the assertion of the clinicians that this is impossible owing to the fact that other diseases show similar results. In fatal cases of pernicious anemia complete autopsies have failed to show any cause for the condition aside from the fatty degeneration of the heart. He thought that the term "splenic anemia" should be dropped. The treatment by bone marrow has been very unsatisfactory in his experience.

Dr. A. E. Taylor of Philadelphia spoke of "The Alterations in the Blood, and Methods of Determination." The blood for examination should be obtained by venepuncture, though the blood obtained from a puncture of the finger, or lobe of the ear, will do very well for a blood count. He has not found centrifugation an accurate procedure, and the Fleischl hemometer is also unreliable. A decrease of red blood-corpuscles is not of vital importance, as the blood, under all circumstances, is always able to carry more oxygen than the system needs, so it seems that the hemoglobin must have some other function than to carry oxygen. He had reached the conclusion that the estimation of the specific gravity of the blood, and not of the hemoglobin, is the important factor in blood examinations, and that the mechanical study of the blood is of more value than the microscopic study.

Drs. S. M. Hamill and D. L. Edsall of Philadelphia presented a paper on "The Salivary and Gastric Functions as Modified in Anemia."

Dr. Wm. Campbell Posey of Philadelphia discussed "Disorders of the Organs of Special Sense in Anemia," confining his remarks to the manifestations of the disease as seen in the eye.

Dr. Judson Daland of Philadelphia said he was glad the point had been brought out that blood should be taken from the veins and not from the finger or lobe of the ear. He was also pleased to hear that Dr. Taylor had noticed the inaccuracies of the Fleischl hemometer, for he had found it difficult to come within ten per cent. of a correct count with this instrument. He hoped that some method of overcoming this objection would soon be devised.

Dr. Max Einhorn of New York read

A FURTHER REPORT OF ISOCHYMIA (DILATATION OF THE STOMACH).

He divided his cases into two classes: (1) Those requiring an operation, and (2) those treated by palliative measures. He has had ten patients operated on for benign stricture of the pylorus, and in one case there had been no dilatation of the stomach made out, nor had there been any vomiting. The diagnosis had been made from the fact that part of the food remained behind in the stomach after the normal period of digestion. In the washing water of the stomach there were also black specks, indicating that there was an ulcer of the stomach. Operation was decided upon on account of the stagnation of food, and the ulcer was excised. The patient recovered and began to gain in weight. This case shows that it is not safe to place much importance upon the size of the stomach. He reported the cases of ten patients with benign stricture of the pylorus, eight of whom recovered and two died. Of the eight reported cured, seven were entirely cured and one was partially cured. In some of the cases of malignant disease the diagnosis had been made from the microscopic examination. If the symptoms do not improve under medical treatment, surgical interference is called for. One of the symptoms of isochymia is retention of food in the stomach, and if this occurs frequently the diagnosis can almost be made from this alone. If this retention of food occurs from stenosis of the pylorus, it should be determined whether this is due to a benign or a malignant cause. In cases of stenosis of the pylorus liquid diet should be ordered, and in serious cases the patient should be nourished by the rectum. His conclusions were that in the majority of cases of isochymia narrowing of the pylorus exists; that the most frequent form of isochymia is dilatation of the stomach; that isochymia produced by malignant tumors should be promptly operated upon; that when not dependent upon a malignant growth an effort should first be made to give relief by palliative measures.

RELATION OF FAT NECROSIS AND THE PANCREAS

was the title of a paper read by **Dr. H. U. Williams** of Buffalo. He said that in the eighty cases upon which his paper was based he had seldom seen any carcinoma of the pancreas, and peritonitis was not usually present. He described his experiments on dogs and cats by which he had produced an inflammation in the pancreas by tying off the organ and lacerating it with hooks.

Dr. James Tyson of Philadelphia made a few remarks upon

THE DIAGNOSIS OF ABDOMINAL EFFUSION AND GROWTHS,

dwelling especially upon the occurrence of tympany in the flanks and presenting models to show how this was to be explained. The occurrence of this phenomenon in several of his patients with abdominal tumors had somewhat mystified his assistants, and had masked the presence of the tumors. In spite of this confusing symptom he had diagnosed the presence of tumors with ascites, and had drawn off seven pints of fluid in two tappings.

THE TREATMENT OF CANCER BY ZINC MERCURIC CATAPHORESIS

was the title of a paper by **Dr. C. B. Massey** of Philadelphia. He gave the histories of several patients treated in this way with perfect success, and exhibited a patient whom he had treated several years ago, and who appeared then to be dying from a sarcoma of the roof of the mouth. The growth had recurred, however, and though it was much smaller than when he operated upon it before, he was now going to perform a second operation. The operation was almost painless, was prompt, bloodless, and complete.

Dr. J. D. Steele of Philadelphia reported a

CASE OF PRIMARY RENAL TUBERCULOSIS,

and read a paper with that title.

Dr. Matthew Woods of Philadelphia read a paper upon his

EXPERIENCE IN THE TREATMENT OF EPILEPSY ACCORDING TO THE METHOD SUGGESTED BY NIEMEYER.

The closing paper of the session was entitled

MEDICINE AS AN EXACT SCIENCE,

and was read by **Dr. W. J. K. Kline** of Washington.

A vote of thanks was then extended to the Chairman, Dr. Musser, for his able management of the business of the section, and the meeting was declared adjourned.

Section on Obstetrics and Gynecology.

(Concluded from page 809.)

Third Day—June 3d.

Dr. Lewis Schooler of Des Moines read a paper on

VAGINAL SECTION IN EXTRA-UTERINE PREGNANCY.

He said that many of us had been taught that the diagnosis of ectopic pregnancy was impossible, and that hence, as there was no diagnosis, there was no treatment. Today we can make a diagnosis with remarkable accuracy. The advantages of the vaginal route are greatest when pus abounds, as infection of the peritoneal cavity follows more certainly if the abdominal route is adopted. The operation is short, and should not be followed by shock or secondary hemorrhage. The bleeding points are also directly under the eye. If the vaginal wall is incised and irrigation and drainage is used, nothing is sacrificed by the operation, whereas abdominal section necessarily implies a sacrifice of ovary and tube. It is urged by some that herniæ are as frequent in the vaginal operation as after the abdominal. This is not true. Healing by first intention in the vaginal operation is not expected, while healing by granulation is encouraged. The strongest argument against the vaginal operation is that it is not a definite operation; that damaged structures are left behind, and that part of the disease is beyond the reach of operation; also, that in pus-cases a cure is not effected and abdominal section is at last the only source of relief. In other cases only a small amount of relief is gained. On the other hand, the abdominal operation is radical, and important organs are too freely sacrificed.

Dr. M. Price of Philadelphia read a paper, entitled

EXTRA-UTERINE PREGNANCY, WITH REPORT OF CASES.

He exhibited a specimen of ectopic gestation at the fourth month, which he said beautifully illustrated the impropriety of the vaginal operation. In all cases of ruptured pregnancy with hemorrhage and shock the accident invariably occurred before the twelfth week. Even those cases which go to term have ruptured at some time, and all these pass through the hands of the general physician. Many of them perish of hemorrhage, septic peritonitis, or obstruction of the bowel because the physician fails to recognize the conditions. Some recover in spite of lack of treatment. These are classed under the head of hematocele. In his own work and that of Dr. J. Price, covering over 175 cases, he has only seen one variety of ectopic pregnancy, namely, the tubal. He has yet to see the first case developing in the broad ligaments. The symptoms are almost pathognomonic. There is usually a history of sterility for a number of years, after which the symptoms follow, *viz.*, sick stomach, intense pain, collapse, and hemorrhage after the second month or a slight discharge as in miscarriage, and after the twelfth week a shedding of almost the entire lining of the uterus. In the case he reported, the patient had an intense feeling of impending death. He thinks we can do no better than to follow the teachings of Lawson Tait. In the last few years it is rare to find a case of extra-uterine gestation in which a diagnosis has not been made. How do these cases go to term? In two cases of Dr. J. Price, both children living, they were enclosed in the amniotic sac, and in one case of his own, at the tenth month with a living child, the amniotic sac also existed. In rupture we operate and find everything but the child, because here the sac is ruptured and the fetus has escaped. The cases can only go to term when the sac fails to rupture. In the case mentioned the placental site extended from the corner of the uterus to the diaphragm, covering everything on the left side of the abdomen. To remove this would have been instant death from hemorrhage. As soon as the diagnosis is made, immediate operation is indicated to avoid the daily and hourly increasing danger to the patient. If the placenta is so fixed that we can remove it radically, although with great risk, we should do so. This failing, clean the face of the placenta, wash out the cavity, and close hermetically, trusting to the future.

Dr. J. Wesley Borée of Washington, D. C., read a paper on

THE VAGINAL ROUTE IN THE SURGICAL TREATMENT OF RUPTURED TUBAL PREGNANCY.

The best variety for the vaginal operation is where the hemorrhage has not been severe, but where the omentum or bowels have prevented upward growth into the abdominal cavity. In these cases, incision through the vagina back of the cervix is the best method. The difficulty lies in differentiating between cases suitable for vaginal and those suitable for abdominal section. In all cases, therefore, the operator should hold himself in readiness to finish through an abdominal incision. He has done six cases by the vaginal route, all promptly recovering without unpleasant symptoms.

Dr. Philander A. Harris of Paterson, N. J., presented a paper on

CLOSURE OF THE ABDOMINAL INCISION.

He stated that probably no condition calls for a secondary operation so frequently as hernia. Until within the past few years through-and-through suturing was the common method employed. He believes, as a routine practice, in first suturing the peritoneum by a modified Lembert's suture with fine catgut, then the aponeurosis with chromicized catgut, next the muscle, and finally the skin and superficial fascia. He employs an interrupted stitch for the aponeurosis. For the skin he does not think it matters what we use; personally, he has been accustomed to employ the so-called Halsted subcutaneous suture. By using kangaroo tendon and not the non-absorbable suture, he avoids abscess and pain. As to the particular structure that produces the tensile strain, it is probably mainly the aponeurosis of the transversalis muscle.

Dr. Franklin H. Martin of Chicago read a paper, entitled

TREATMENT OF RETROVERSION OF THE UTERUS,

in which he gave an amusing satirical review of the discussion of Dr. Clarke's paper. He claimed that no scientific gynecologist should adopt any routine treatment for retrodisplacement, but should vary the treatment to suit the case. The men who condemn Alexander's operation are those who have not done it frequently enough to understand it. No one should express his opinion until he had done at least 100 operations, when he could not condemn it. Hernia never results from Alexander's operation. The operation has but a small range of usefulness, namely, in retroversion without adhesion or surrounding inflammatory conditions. It should not be done in prolapse unless the support is restored by a simultaneous operation. The round ligaments prevent retrodisplacement. He ties the two ligaments together under the skin over the pubes, thus shortening them. Ventrofixation is of service in women who will not become pregnant. He employs Fowler's operation in doing the fixation, in which the urachus is made to support the uterus.

Dr. J. J. Maker of New York presented a paper on

ONE HUNDRED CASES OF ATRESIA AND STENOSIS OF THE VAGINA IN LABOR, THIRTEEN OF WHICH WERE FATAL.

These cases were gathered from the most recent medical literature. The common causes of atresia were transverse membranes or septa, tubular contraction, and transverse bands. He classifies the cases as membranes or septa, stenosis, and bands. There were forty-five contractions in the middle third of the vagina, and some cases in which the site of the atresia was not mentioned, it is probable that ten additional could be placed here in the middle third, making probably about 60 to 65 per cent. of the cases. In 15 of the membranes no opening was found, 31 were firm, 12 cicatricial, 10 cartilaginous. In 20 cases the obstruction measured in thickness 1½ to 12 mm.; in 4 there was stenosis of the entire vagina, and in 1 of the anterior half. As to causation, 42 cases were congenital, 45 post-partum. Operations on the pelvis, forceps, cephalotomy, embryotomy, rough removal of the placenta, tedious labor, were all mentioned as causes. Four cases were traumatic. The post-operative cases came from attempts to close vesicovaginal fistulæ. There were 33 complications, with deaths of seven mothers and twenty children. There were 4 cases of rupture of the uterus; 67 cases were treated by incision, with seven maternal deaths. In 2 cases the thermocautery was used. In 13 cases the septa were ruptured by the advancing head. Embryotomy was done in two cases, with death of both mothers. The fact that between 70 and 80 per cent. of the cases were found in the middle third of the vagina would indicate some increase in the muscular tonus of this portion. The proper course to pursue is to obliterate the obstruction as soon as discovered during labor, or before labor if possible.

Dr. J. H. Kellogg of Battle Creek, Mich., read a paper, entitled

RATIONAL GYNECOLOGY,

in which he briefly called attention to a class of conditions which does not attract the attention it deserves. He claimed that pelvic disease is not always purely local. The surgeons forget this, and often remove a hypersensitive ovary or perform a hysterectomy because the patient is suffering from general nervous exhaustion. From a study of his case-book he finds that 52 per cent. of the cases showed displacement of the abdominal viscera without associated displacement of the pelvic viscera, and only 6 per cent. showed the reverse condition. Visceral displacement in pelvic cases, therefore, is not a distinct pathologic entity, but is associated generally with displacement of the abdominal viscera as a primary cause. Rational gynecology therefore, includes the treatment and restoration of the abdominal viscera as well. He believes that the backache and other symptoms are due to general visceral prolapse, and not merely to displacement of the pelvic organs. Retrodisplacement is favored by lack of obliquity of the pelvis.

Dr. J. F. Baldwin of Columbus read a paper on

THE TECHNIC OF ABDOMINAL HYSTERECTOMY,

in which he said that the abdomen is opened in the usual way by as free an incision as is necessary. The adhesions are freed, the uterus is drawn up into the incision, and the most accessible broad ligament drawn out and the ovary cut loose after the application of a clamp. The other ligament is treated in the same way. Clamps are then applied below, and anterior and posterior flaps of peritoneum made, the broad ligaments are then separated, and the uterine arteries found and ligated. A V-shaped division of the uterine body is then made. In suitable cases he ligates on one side and then removes the mass according to Kelly's method. The patient is then placed in the Trendelenburg posture, and the uterine arteries found, drawn out, and ligated. The round ligaments are then caught with forceps and the clamp removed from the broad ligament. The ovarian arteries are then drawn out and ligated. Gauze is passed down through the cervix into the vagina. He closes the peritoneal flaps over the cervix with kangaroo tendon and a running suture, thereby preventing raw surfaces, to which adhesions may occur. The operation is short—forty minutes—there is almost no hemorrhage and shock, and convalescence is short also. The ligature placed around the uterine artery is outside the uterine tissue. The danger of intestinal adhesions is *nil.* The use of clamps on the broad ligament saves time.

Dr. Marcy of Boston was pleased with the introduction of gauze from above downward. He would suggest a continuous Lambert suture in closing the peritoneal surfaces. This becomes buried when traction is made upon it.

Dr. Henry P. Newman of Chicago read a paper on

THE TREATMENT OF INEVITABLE ABORTION.

He stated that 85 to 90 per cent. of married women abort at least once. The dangers are hemorrhage and sepsis, subinvolution of the uterus, uterine displacement, salpingitis, and ovaritis. He is opposed to the expectant plan of treatment. We have here a gynecologic and not an obstetric condition, hence he prefers to empty the uterus at once. His paper refers to expulsion of the fetus during the first three months. Kliehrssen records 150 cases of abortion treated by the active method, with only two deaths. Newman observes the same precaution as in doing an abdominal section.

Dr. Cartledge of Louisville presented a large ovarian cyst of thirteen-years' growth, taken from a woman thirty-seven years of age. The circumference of the woman at the umbilicus was 79 inches, the distance from the ensiform to the pubes was 49 inches. Twenty gallons of fluid were removed from the cyst before the anesthetic was given, and afterward ten gallons more were taken away. There were terrific adhesions, and the operation took two hours. The woman survived the operation until the sixth day, when internal obstruction developed, and she died the evening of the same day. The water removed weighed 240 pounds, the sac weighed 5 pounds more, making a total of 245 pounds, 50 pounds larger than any other reported cyst.

FOURTH DAY—JUNE 4TH.

Dr. Anna M. Fullerton of Philadelphia presented a paper, entitled

STUDIES IN GYNECOLOGY FROM THE SERVICE OF THE WOMAN'S HOSPITAL OF PHILADELPHIA.

She believes that in the future we must pay more attention to the constructive part of gynecology, the making of healthy women. The weakened tissues of young girls due to poor hygiene, predispose to menstrual and uterine disease. She does not believe that such cases require little local treatment, which, under the use of cocain is quite easy on account of the relaxed tissue. The tonicity of the uterine supports and muscle, and improvement of the blood are the indications in the treatment. All of the clothing should be loosened. If too tight, it produces uterine displacement with all its attendant ills. Abdominal breathing should be practised, and the judicious use of the bicycle to stimulate the abdominal muscles. In cases of prolapse of the uterus the patient herself may introduce a sterile silk sponge into the vagina, after anointing it with boroglycerid, and push it up by means of a glass rod into the posterior cul-de-sac. The condition of puerperal subinvolution predisposes to inflammation and structural change. Bicycle-riding in pregnancy in two cases resulted in one in an extremely easy labor, and a beneficial result in the other patient, who is still pregnant. The diet during pregnancy will largely influence the process of lactation.

Dr. J. Milton Duff of Pittsburg read a paper on

SOME REFLEX DISTURBANCES DUE TO PELVIC DISEASE, WITH REPORT OF CASES,

which was fully discussed. Dr. Kelly especially emphasizing the relation existing between the minor pelvic affections, especially retrodisplacement. and neurasthenia.

DR. ALBERT H. TUTTLE of Cambridge read a paper on the

INJURIES OF PARTURITION, THE TIME, METHOD, AND REASON FOR REPAIR,

and DR. J. M. EMMERT of Atlantic City presented a paper on

FIBROID TUMORS OF THE VAGINA, WITH REPORT OF CASE.

The remaining papers on the program were read by title.

REVIEWS.

TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY. Vol. VII. Part III. Thirty-second Annual Meeting. Hartford: Published by the Society, 1897.

THE amount of original scientific work presented at the last meeting of this Society is a convincing proof, were any needed, of the progressive spirit which animates the ophthalmologists of our country. To all interested in this specialty, as well as to many workers in the wider field of general medicine, this volume of the transactions will prove a store-house of valuable information. Where so much is offered, a choice is very difficult and a review of the important contributions would contain most of the forty or more papers mentioned in the table of contents. Among those of special interest are: "The Course and Prognosis of Orbital Tumors as Influenced by Surgical Operations for Their Removal," by Dr. C. S. Bull; "Ophthalmic Conditions in Case of Cerebellar Tumor," by Dr. C. A. Oliver; an able contribution on the "Use of Mercury in Traumatic irido-Choroiditis," by Drs. C. W. Kollock and S. Theobald's practical treatise on "Sterilization of Cataract Instruments." Successful application of Röntgen's discovery to ophthalmic diagnosis is reported in the cases of Drs. C. H. Williams and C. F. Clark.

A GUIDE TO THE CLINICAL EXAMINATION OF THE BLOOD FOR DIAGNOSTIC PURPOSES. By RICHARD C. CABOT, M.D. New York: William Wood & Co., 1897.

THE clinical examination of the blood has become a routine of such imperative necessity as a diagnostic aid and confirmer, that it is quite remarkable that no text-book on the subject has previously appeared in the English language. The present one, with some exceptions presently to be noted, covers the field very well and includes within its pages most of what is regarded as generally accepted truth.

The author, in the introduction, speaks of the scope and value of blood examinations. This is followed by a description of the methods of making such examinations, of the apparatus employed, and the different stains. The physiology and the general pathology of the blood are next considered, and the remainder of the book—more than half—is devoted to the special pathology of the blood. In these chapters, the variations in the constituents of this circulating fluid are discussed in detail.

Within the scope of this review it is impossible to do more than point out a few misconceptions and to utter a note of warning. The misleading results and misinterpretations after examination of the blood, which physicians acquire and are led into are due, as a rule, to imperfect training, and it is barely possible that a book like the one under consideration may serve only to increase general disrespect for minute clinical methods. Yet if the book is read and studied as it should be it may be the means of fostering a spirit of accuracy in clinical diagnosis among those who have considered themselves incompetent to follow the rapidly increasing methods of microscopic aids in diagnosis.

The author, unmindful of Ehrlich's admonition that the evaporation from the hand may change the granules in the white cells, recommends the holding of the cover-glass in the hand rather than in a forceps (p. 7). The figures on page 19 attributed to Dr. Franklin White, represent devices published by Ehrlich. No mention is made of fixing blood to be examined by the formalin method so much praised by recent observers. The valuable paper of Kraus of Graz, on the determination of the alkalinity of the blood is not referred to.

These are but minor criticisms, it is true, and it is not intended that they shall detract from the praise of the book; for it is a well-conceived, well-written, almost complete hand-book and deserves a wide circulation.

A large bibliography is appended to the work. The illustrations are fair only, most of the lithographic plates not being comparable to the originals from which they were borrowed. The printing and the binding are good.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. From models in the Museum of the Saint Louis Hospital, Paris. With text by BESNIER, FOURNIER, and others. Price $3.00 per part. Philadelphia: W. B. Saunders, 1897.

THE plates of this atlas are photolithochromes and the accuracy of their coloring is admirable. It is indeed remarkable when it is remembered that these illustrations are not taken from life, but from the models in the well-known collection of the Saint Louis Hospital in Paris. The explanatory text accompanying the plates contains a wood-cut copy of the plate with numbered lines pointing to the various lesions of which a detailed description is given. This serves to make the description extremely clear and instructive to the reader. A concise history of the case is usually given in the text, and the etiology, pathology, and treatment of the disease is briefly discussed. To the specialist in dermatology the text of this work will undoubtedly prove as attractive as the plates, and the views and opinions presented by the authors, as well as by the English editor, will be read with pleasure and profit.

The claim made by the publisher that the illustrations will chiefly represent typical cases of common diseases of the skin is hardly borne out in most of the parts. A glance at the captions appended to the plates will establish the fact that about one-half of the cases might be justly classed as rare or uncommon forms of cutaneous disease.
